SUMMARY

We consider semiparametric transition measurement error models for longitudinal data, where one covariate is measured with error and no distributional assumption is made for the underlying unobserved covariate. An estimating equation approach based on the pseudo conditional score method is proposed. We show the resulting estimators of the regression coefficients are consistent and asymptotic normal. We derive the semiparametric efficiency score and study the efficiency loss of the pseudo conditional score estimator. In the presence of validation data, we propose a one-step estimator that achieves the semiparametric efficient bound. Simulation studies are conducted to examine the small-sample performance of our estimator. A real data set is analyzed for illustration.

Some Key words: Asymptotic efficiency, Conditional score method, Functional modeling, Measurement Error, Longitudinal data, Semiparametric inference, Transition models.
1. INTRODUCTION

Longitudinal data are common in health sciences research, where repeated measures are obtained for each subject over time. Diggle, et al. (2002) provide a comprehensive overview of statistical methods for analyzing longitudinal data. One class of longitudinal models is the transitional model, where the conditional mean of an outcome at the current time point is modeled as a function of its values at the previous time points and covariates (Diggle, et al., 2002, Chapter 10). This model is useful when one is interested in studying the effects of covariates and the past responses on the current response or predicting the future response given the past history. The within-subject correlation is easily accounted for by conditioning on the past responses, and the model can be easily fit within the generalized linear model framework. Transition models have been studied in a number of literatures and applications (Young et al. 1999, Heagerty 2002, Have and Morabia 2002, Yu et al. 2003, Yang et al., Dunson 2003, Roy and Lin 2005).

Measurement error is a common problem in longitudinal data collection, due to reasons such as equipment limitation, longitudinal variation, or recall bias. Classical covariate measurement error examples include CD4 counts in AIDS studies (Tsiatis, Degruttola and Wulfsohn 1995), blood pressure and fat intake in nutritional studies (Carroll, Ruppert, and Stefanski 1995). In one study from the AIDS Costs and Services Utilization Survey (ACSUS) (Berk, Maffeo and Schur 1993) which consists 2487 subjects in 10 randomly selected U.S. cities with the highest AIDS rates, one main outcome was whether an interviewee had hospital admission (yes/no) during the past 3 months and a question of interest is to predict how CD4 count affects the risk of future hospitalization given subject’s past history. A natural model for analyzing this data is to use transition model. However, CD4 count is known to contain measurement errors due to its substantial variability (Tsiatis et al. 1995) and another source of error in this study is due to the fact that CD4 count was not measured at the time of each interview but abstracted from each respondent’s most recent medical record.

For independent data, a comprehensive review on measurement error methods is given in Fuller (1987) and Carroll, et al. (1995). It is well known in traditional regression settings that ignoring covariate measurement error would lead to attenuated regression coefficient estimators. For longitudinal data, Buonaccorsi, Demidenko and Tosteson (2000) and Wang, et al. (1998) among others considered measurement error in mixed effects models. Limited work has been done for modeling measurement error in transition models. Schmid, Segal and Rosner (1994) and Schmid (1996) studied measurement error in first-order autoregressive models for continuous longitudinal outcome. Pan, Lin and Zeng (2006) proposed maximum likelihood estimation in generalized transitional measurement error mod-
els by assuming the repeated measures of the unobserved covariate follows a parametric multivariate normal distribution with the first order auto-regressive or AR(1) correlation structure. Consistency of the maximum likelihood estimator requires that the normality assumption holds and the correlation structure of the repeated measures of the unobserved covariate is correctly specified. However, in reality, such a normality assumption is often too strong. See the histogram of CD4 count of the ACSUS study in Figure 1, which shows considerable non-normality even after a log transformation. Further, the correlation structure of the repeated measures of the unobserved covariate is difficult to be specified correctly. It is hence desirable to develop a semiparametric method which leave the distribution of the repeated measures of the unobserved covariate fully unspecified. We develop such a semiparametric method for transition measurement error models in this paper.

For independent data, estimation in measurement error models without specifying a distribution for the unobserved covariate has been considered by several authors, when validation data are available. Stefanski and Cook (1995) proposed the SIMEX method, which is simple to implement but the resulting estimator is often inconsistent. Carroll et al. (1991) discussed using the validation data to obtain a kernel estimator of the density for the error-prone covariate then plugging it into the score equation to produce a consistent regression coefficient estimator. Recently, Schafer (2001) considered using the EM algorithm to maximize the observed likelihood function by treating the distribution for the unobserved covariate as a discrete function on a finite set of points. However, neither of these approaches is applicable to longitudinal data. A major difficulty is that the unobserved covariate has repeated measures which are likely to be correlated. The kernel method of Carroll et al. (1991) requires large validation data due to the curse of dimensionality needed for constructing a multivariate kernel density estimator. For the same reason, the number of points chosen for estimating the multivariate distribution of Schafer (2001) has to be unrealistically large.

Instead of estimating the multivariate distribution of the repeated measures of the unobserved covariate, we propose two semiparametric methods in this paper. Our first approach is based on an estimating equation method by modifying the conditional score method, which was originally proposed for measurement error regression for independent data by Stefanski and Carroll (1987). However, its generalization to the transition model is not trivial for longitudinal data in the presence of repeated measures of the unobserved covariate. We next derive the semiparametric efficiency score and study the efficiency loss of the pseudo conditional score estimator. In the presence of validation data, we propose a one-step estimator and show it reaches the semiparametric efficiency bound.

The rest of the paper is structured as follows. In §2, we present the semiparametric transition mea-
measurement error model for longitudinal data. In §3, we study the asymptotic bias when the distribution of the unobserved covariate is misspecified. In §4, we derive the general conditional score estimating equation and study the theoretical properties of the conditional score estimator, and apply the approach to both the linear and logistic transition models, then illustrate the method using simulation studies and an analysis of the ACSUS data. In §5, we derive the semiparametric efficiency score, and study efficiency loss of the pseudo conditional score estimator. When validation data are available, we propose a one-step estimator that is shown to be semiparametric efficient. Some numerical results are provided. Discussions are given in Section 6.

2. SEMIPARAMETRIC TRANSITION MEASUREMENT ERROR MODEL FOR LONGITUDINAL DATA

Suppose we observe longitudinal data from \( n \) subjects, and each subject has \( m \) repeated measures over time. Let \( Y_{ij} \) be the response at time \( j \) (\( j = 1, \cdots, m \)) of subject \( i \) (\( i = 1, \cdots, n \)). Let \( W_{ij} \) be a scalar observed error-prone covariate, which measures the unobserved covariate \( X_{ij} \) with error. Let \( Z_{ij} \) be a vector of covariates that are accurately measured. The transition model assumes the conditional distribution of \( Y_{ij} \) given the history of the outcome \( Y \) and the history of the true covariates \( X \) and \( Z \) satisfies the \((q, r)\)-order Markov property (Ch 10, Diggle et al., 2002) and belongs to the exponentially family. Specifically, we assume that \( Y_{ij} \) depends on the past history only via \( Y_{i;j,i;1}, \cdots, Y_{i;j,i;q} \) and \( X_{ij}, \cdots, X_{i,j-r+1}, Z_{ij}, \cdots, Z_{i,j-r+1} \) for \( j > (r - 1) \vee q \), where \((r - 1) \vee q = \max(r - 1, q)\). Furthermore, the conditional distribution of \( Y_{ij} \) follows the exponential family

\[
f(Y_{ij}|\bullet) = \exp \left\{ (Y_{ij}\eta_{ij} - b(\eta_{ij}))/a \phi + c(\bullet, \phi) \right\},
\]

where \( \bullet = \{Y_{i,j-1}, \cdots, Y_{i,j-q}, X_{ij}, \cdots, X_{i,j-r+1}, Z_{ij}, \cdots, Z_{i,j-r+1}\} \), \( f(\cdot) \) denotes a density function, \( a \) is a prespecified weight, \( \phi \) is a scale parameter, and \( b(\cdot) \) and \( c(\cdot) \) are specific functions associated with exponential family. We assume a canonical generalized linear model (McCullagh and Nelder, 1989) for \( \mu_{ij} = E(Y_{ij}|\bullet) = b'(\eta_{ij}) \) as

\[
g(\mu_{ij}) = \eta_{ij} = \beta_0 + \sum_{k=1}^{q} \alpha_k Y_{i,j-k} + \sum_{l=1}^{r} \{ \beta_{zl} X_{i,j-l+1} + \beta_{zl} Z_{i,j-l+1} \},
\]

where \( g(\cdot) \) is a canonical link function and satisfies \( g^{-1}(\cdot) = b'(\cdot), \beta_0, \alpha_k (k = 1, \cdots, q), \beta_l = (\beta_{zl}, \beta_{zl})^T \) \( (l = 1, \cdots, r) \) are regression coefficients. Additionally, we treat \( Y_{i1}, \cdots, Y_{i,(r-1)\vee q} \) as initial states of this transition and assume that their distribution does not depend on \( \beta \)'s and \( \alpha \)'s.

We assume that the measurement error is additive as

\[
W_{ij} = X_{ij} + U_{ij},
\]
where the measurement error $U_{ij}$ are independent of the $X_{ij}$ and are independent and identically distributed and follow $U_{ij} \sim N(0, \sigma^2_u)$ for a known variance $\sigma^2_u$. Pan, et al. (2006), in their maximum likelihood estimation approach, assumed a multivariate normal distribution for the unobserved covariate vector $\{X_{i1}, \ldots, X_{im}\}$ with an auto-regressive correlation structure. The consistency of their maximum likelihood estimator requires the normality assumption. In this paper, we leave the joint distribution of $\{X_{i1}, \ldots, X_{im}\}$ fully unspecified and proceed with semiparametric estimation.

We assume that measurement error is non-differential, i.e., for each subject $i$, conditional on his/her history of $Y$ and the true covariates $X, Z$, $f(Y_{ij})$ and $f(W_{ij}|X_{ij})$ are independent, i.e.,

$$f(Y_{ij}, W_{ij}| \bullet) = f(Y_{ij}| \bullet)f(W_{ij}|X_{ij}),$$

where $\bullet$ was defined in (1). This means conditional on the true unobserved covariate $(X, Z)$, the observed covariate $W$ does not contain additional information about $Y$. We further assume that conditional on the past history of $(Y, X, Z)$, the covariates $(X_{ij}, Z_{ij})$ only depends on the past history of the covariates of $(X, Z)$, i.e.,

$$f(X_{ij}, Z_{ij}|Y_{i,j-1}, \ldots, Y_{i1}, X_{i,j-1}, \ldots, X_{i1}, Z_{i,j-1}, \ldots, Z_{i1}) = f(X_{ij}, Z_{ij}|X_{i,j-1}, \ldots, X_{i1}, Z_{i,j-1}, \ldots, Z_{i1}).$$

It follows that the log-likelihood function for the observed data is given by

$$\sum_{i=1}^{n} \log \int \prod_{j=(r-1)q+1}^{m} f(Y_{ij}| \bullet)f(W_{ij}|X_{ij})f(X_{ij}, Z_{ij}|X_{i,-j}, Z_{i,-j})dX_{i1}\cdots dX_{im},$$

where $\bullet$ is the same as before, $f(Y_{ij}| \bullet)$ is given in (1) and $f(W_{ij}|X_{ij})$ is the normal density under model (3), $X_{i,-j} = (X_{i,j-1}, \ldots, X_{i1})^T$ and a similar definition of $Z_{i,-j}$.

3. ASYMPTOTIC BIAS ANALYSIS OF THE MAXIMUM LIKELIHOOD ESTIMATOR WHEN THE DISTRIBUTION OF $X$ IS MISSPECIFIED

To reveal the importance of our interest in leaving the distribution of the unobserved covariate $X$ unspecified, we first study the asymptotic bias in maximum likelihood estimator when the distribution of $X$ is misspecified. To highlight the key issue, without loss of generality, we focus on the case of $q = 1$ and $r = 1$ in (2) and $X$ being the only covariate in the regression; that is, we consider the following simple generalized linear transition model:

$$g(\mu_{ij,x}) = \beta_0 + X_{ij}\beta_x + Y_{ij-1}\alpha.$$  \hspace{1cm} (5)

To study the asymptotic bias of the maximum likelihood estimator when the distribution of $X$ is misspecified, we assume that the true model for $X_{ij}$ follows a first-order Markov model

$$X_{ij} = \gamma_0 + X_{ij-1}\gamma_x + \epsilon_{xij},$$  \hspace{1cm} (6)
where \( e_{xij} \) are independent of the \( U_{ij} \) in the error model (3) and are independent \( N(0, \sigma_x^2) \). Equivalently, under the general stationary assumption, the true \( X \) model can be rewritten as

\[
X_i = 1_i \frac{\gamma_0}{1 - \gamma_x} + e_{xi} = 1_i \mu_x + e_{xi},
\]

where \( 1_i \) is an \( m \times 1 \) vector of ones, \( \gamma_0/(1 - \gamma_x) = \mu_x \) is the mean of \( X_i \), and \( e_{xi} \) is an AR(1) Gaussian process with mean 0 and covariance matrix \( \Sigma_{xi} \), whose \((j,k)\)th element is \( \sigma_x^2(1 - \gamma_x^2)^{-(j-k)} \). In the following context, we name this model as the AR(1) model.

We study the asymptotic biases in maximum likelihood estimators when one misspecifies the \( X \) model as an independent model. That is, the incorrect \( X \) model used in the maximum likelihood estimation is no longer a first-order autoregressive model, but instead, a model given by

\[
X_i = 1_i \mu_x + \tilde{e}_{xi},
\]

where \( \tilde{e}_{xi} \sim N(0, \sigma_x^2 I) \) and \( \mu_x \) and \( \sigma_x^2 \) are two unknown parameters. Equivalently, one misspecifies the observations \( X_{ij} \) as generated from independent and identically distributed \( N(\tilde{\mu}_x, \tilde{\sigma}_x^2) \). We name this model as the independent model.

Some more notation is as follows. Denote the asymptotic limits of the maximum likelihood estimators of \( \theta_Y = (\beta_0, \beta_x, \alpha)^T \) and \( \theta_X = (\tilde{\mu}_x, \tilde{\sigma}_x^2)^T \) based on the misspecified independent \( X \) model as \( \theta_{Y,\text{indep}} = (\beta_0, \tilde{\mu}_x, \tilde{\sigma}_x^2, \alpha, \sigma_\epsilon^2)^T \) and \( \theta_{X,\text{indep}} = (\beta_0, \tilde{\mu}_x, \tilde{\sigma}_x^2, \alpha, \sigma_\epsilon^2)^T \). Furthermore, define the reliability coefficient by

\[
\lambda = \frac{\text{var}(X_{ij})}{\text{var}(Y_{ij})} = \frac{\sigma_x^2(1 - \gamma_x^2)^{-(1/2)}}{\sigma_\epsilon^2(1 - \gamma_x^2)^{1/2} + \sigma_x^2}.
\]

In the following subsections, we investigate the asymptotic biases of the maximum likelihood estimators for Gaussian outcomes and non-Gaussian outcomes separately.

### 3.1 Asymptotic Biases Under the Linear Transition Model for Gaussian Responses

In this section, we study the asymptotic biases of the maximum likelihood estimators under a misspecified \( X \) model when \( Y \) follows a linear transition model

\[
Y_{ij} = \beta_0 + X_{ij}\beta_x + Y_{ij-1}\alpha + \epsilon_{ij}, \quad \epsilon_{ij} \overset{i.i.d.}{\sim} N(0, \sigma_\epsilon^2).
\]

Under the AR(1) \( X \) model, the results of Theorem 1 of Pan et al. (2006) show that \( Y_{ij} \) given the observed data \( W_{ij}, Y_{ij-1} \) satisfies

\[
E(Y_{ij} | W_{ij}, Y_{ij-1}) = \beta_0^* + \lambda^* \beta_x W_{ij} + (\alpha + \lambda^{**}) Y_{ij-1},
\]

where \( \beta_0^* \) is some constant, and

\[
\lambda^* = \frac{\text{var}(X_2)\text{var}(Y_1) - \text{cov}^2(X_2, Y_1)}{\{\text{var}(X_2) + \sigma_x^2\}\text{var}(Y_1) - \text{cov}^2(X_2, Y_1)}.
\]
\[
\lambda^{**} = \frac{\beta_x \sigma^2 \text{cov}(X_2, Y_1)}{\{\text{var}(X_2) + \sigma^2\} \text{var}(Y_1) - \text{cov}^2(X_2, Y_1)}.
\]

Under the independent X model, one can easily show that the \(Y_{ij}|W_{ij}, Y_{ij-1}\) model takes the form

\[
E(Y_{ij}|W_{ij}, Y_{ij-1}) = \beta_{0,\text{indep}} + \lambda \beta_{x,\text{indep}} W_{ij} + \alpha_{\text{indep}} Y_{ij-1}.
\]

Thus, we obtain the following result.

THEOREM 1 Under the conditions that \(|\alpha| < 1\) and \(|\gamma_\| < 1\), we have

\[
\beta_{x,\text{indep}} = \frac{\lambda^*}{\lambda} \beta_x, \quad \alpha_{\text{indexp}} = \alpha + \lambda^{**}.
\]

Furthermore, Theorem 2 in Pan et al. (2006) shows that \(\lambda^* \leq \lambda\) and \(\lambda^{**}\) has the same sign as \(\gamma_x\). As a result, we obtain \(|\beta_{x,\text{indep}}| \leq |\beta_x|\); \(\alpha_{\text{indep}}\) is greater than \(\alpha\) when \(\gamma_x > 0\), while less than \(\alpha\) when \(\gamma_x < 0\). It follows that the maximum likelihood estimator of \(\beta_x\) under the misspecified X model is still attenuated, but its bias is less than the corresponding naive estimate when measurement error is ignored by of replacing \(W\) by \(X\) in (8), since \(\lambda < 1\). The maximum likelihood estimator of the coefficient of the historical response \(\alpha\) under the misspecified independent X model is equal to its corresponding naive estimator when the measurement error is ignored. Clearly, if in the true model \(\gamma_x = 0\), i.e., the AR(1) model is equivalent to the independent model, \(\beta_{x,\text{indep}}\) and \(\alpha_{\text{indep}}\) are consistent estimators of the true parameters \(\beta_x\) and \(\alpha\).

In Figures 2, we numerically evaluate the asymptotic relative biases in \(\beta_{x,\text{indep}}\) and \(\alpha_{\text{indep}}\) as a function of the measurement error variance \(\sigma^2_u\). The parameter configurations are that \(\beta_0 = -1, \beta_x = 1, \alpha = 0.5, \sigma^2 = 1, \) and \(\gamma_0 = 0.4, \gamma_x = 0.6, \sigma^2_x = 0.5\). The relative bias is defined as the bias of a parameter divided by its true value. The figure clearly shows that the maximum likelihood estimate of \(\beta_x\) under the independent X model is attenuated. The maximum likelihood estimate of \(\alpha\) under the independent X model is inflated. The biases become more severe as \(\sigma^2_u\) increases.

3.2. Asymptotic biases in the generalized linear transition model for non-gaussian response

When the response \(Y\) is non-Gaussian, the bias analysis of the maximum likelihood estimator under the misspecified X model is much more complicated, since the variance structure of the outcome depends on the measure structure. Closed form expressions of \(\beta_{x,\text{indep}}\) and \(\alpha_{\text{indep}}\) are generally unavailable, and numerical calculations are hence needed. We first describe the general theoretical results
under the generalized linear transition model (5), then show as an example the detailed numerical calculation results of the asymptotic bias analysis in the logistic transition model
\[
\text{logit}\{P(Y_{ij} = 1|X_{ij}, Y_{ij-1})\} = \beta_0 + X_{ij}\beta_x + Y_{ij-1}\alpha.
\] (9)

The maximum likelihood estimator \((\theta_{Y,\text{indep}}, \theta_{X,\text{indep}})\) under the misspecified independent \(X\) model maximizes the log-likelihood
\[
n^{-1} \sum_{i=1}^{n} \ell_{\text{indep}}(Y_i, W_i; \theta_{Y,\text{indep}}, \theta_{X,\text{indep}}),
\]
where \(\ell_{\text{indep}}(Y_i, W_i; \theta_{Y,\text{indep}}, \theta_{X,\text{indep}})\) is the log-likelihood function of the \(i\)th subject under the independent model (5),(3) and (7). Suppressing the subscript \(i\), the asymptotic limit of the maximum likelihood estimate \((\theta_{Y,\text{indep}}, \theta_{X,\text{indep}})\) maximizes the probability limit (as \(n \to \infty\)) of the independent log-likelihood, which equals \(E\{\ell_{\text{indep}}(Y, W; \theta_{Y,\text{indep}}, \theta_{X,\text{indep}})\}\), where the expectation is taken with respect to \((Y, W, X)\) under the true models (5),(3) and (6). To compute this expectation, since under the independent \(X\) model, \(X_{ij} = (1-\lambda)\mu_{x,\text{indep}} + \lambda W_{ij} + e_{wij}\), where \(e_{wij} \sim N(0, (1-\lambda)\sigma_x^2_{\text{indep}})\), we plug this expression into the generalized linear transition model (5) and obtain the following equation for the conditional mean of \(Y_i\) given \(W_i, Y_{ij-1}\), and \(e_{wij}\) as
\[
g(\mu_{ij,w}) = \{\beta_0_{\text{indep}} + (1-\lambda)\mu_x_{\text{indep}}\beta_x_{\text{indep}}\} + W_{ij}\lambda\beta_{x,\text{indep}} + Y_{ij-1}\alpha_{\text{indep}} + \beta_{x,\text{indep}}e_{wij}.
\] (10)

Therefore, the joint log-likelihood function for \(Y_i\) and \(W_i\) under the misspecified independent \(X\) model is
\[
\ell_{\text{indep}}(Y_i, W_i; \theta_{\text{indep}}) = \log \int L_{\text{indep}}(Y_i|W_i, e_{wi}; \theta_{Y,\text{indep}}, \theta_{X,\text{indep}})dF(e_{wi})
\]
\[
= \log \int L_{\text{indep}}(Y_i|W_i, e_{wi}; \theta_{Y,\text{indep}}, \theta_{X,\text{indep}})\sqrt{(1-\lambda)\sigma_x^2_{\text{indep}}}d\Phi(e_{wi}),
\]
where \(L_{\text{indep}}(Y_i|W_i, e_{wi}; \theta_{Y,\text{indep}}, \theta_{X,\text{indep}})\) is the conditional density of \(Y_i\) given \(W_i\) and \(e_{wi}\) based on the model (10). Particularly, when \(Y_i\) is binary,
\[
L_{\text{indep}}(Y_i|W_i, e_{wi}; \theta_{Y,\text{indep}}, \theta_{X,\text{indep}}) = \prod_{j=1}^{m} \{g^{-1}([\beta_0_{\text{indep}} + (1-\lambda)\mu_{x,\text{indep}}\beta_{x,\text{indep}} + W_{ij}\lambda\beta_{x,\text{indep}} + Y_{ij-1}\alpha_{\text{indep}} + \beta_{x,\text{indep}}e_{wij}]Y_{ij})
\]
\[
\times [1 - g^{-1}([\beta_0_{\text{indep}} + (1-\lambda)\mu_{x,\text{indep}}\beta_{x,\text{indep}} + W_{ij}\lambda\beta_{x,\text{indep}} + Y_{ij-1}\alpha_{\text{indep}} + \beta_{x,\text{indep}}e_{wij}]1-Y_{ij})]\}
\]
Together with using Gauss-Hermite quadrature and Monte-Carlo simulations in calculating numerical integrations, the expectation \(E\{\ell_{\text{indep}}(Y, W; \theta_{\text{indep}})\}\) is evaluated, which is a function of \(\theta_{\text{indep}}\) and the true value of \(\theta\).
As an example, we perform the detailed numerical calculations for the asymptotic limit of the maximum likelihood estimator under the misspecified independent $X$ model for binary outcomes using the logistic transition model (9). Figure 3 shows the asymptotic relative biases in $\beta_{\text{x,indep}}$ and $\alpha_{\text{indep}}$ a function of the measurement error variance $\sigma_u^2$. The parameter configurations are the same as those in the linear transition model case. A similar pattern to Figure 2 is observed and as $\sigma_u^2$ increases, the biases become larger.

4. THE PSEUDO CONDITIONAL SCORE METHOD

4.1 The pseudo conditional score estimating equation

Estimation by directly maximizing the likelihood function (4) requires a parametric specification of the density function of $\{X_{i1}, \ldots, X_{im}\}$ and high dimensional integration, and is subject to bias if the distribution of $X$ is misspecified as shown in our asymptotic bias analysis. It is hence desirable to construct a more robust estimator that does not require specifying the distribution of $X$. We propose in this section a pseudo conditional score method.

Specifically, in a similar spirit of Stefanski and Carroll (1987), we pretend $\theta$ to be known but treat the $X_{ij}$ as fixed parameters by writing $X_{ij}$ as $x_{ij}$, and calculate sufficient statistics for $(x_{i1}, \ldots, x_{im})$, and construct score equations of model parameters of interest based on the conditional likelihood function of the observed data given the sufficient statistics. Unfortunately, due to the transition structure and the possibly nonlinear link function in (1), sufficient statistics for $x_{ij}$ based on the distribution of $Y_i = (Y_{i1}, \ldots, Y_{im})$ and $W_i = (W_{i1}, \ldots, W_{im})$ do not exist except for the linear transition model with normal errors. This makes the task of directly adopting the conditional score method of Stefanski and Carroll (1987) to our setting difficult. However, we note that for each $j = (r - 1) \lor q + 1, \ldots, m$, the conditional density of $(Y_{ij}, W_{ij}, \ldots, W_{i,j-r+1})$ given $(Y_{i-}, Z_{i-}, Z_{ij})$ and $(x_{ij}, x_{i-})$ is given by

$$\exp \left[ Y_{ij}(\beta_0 + \sum_{k=1}^{q} \alpha_k Y_{i,j-k} + \sum_{l=1}^{r} (\beta_{xl} x_{i,j-l+1} + \beta_{zl} Z_{i,j-l+1}) \right] / a \phi$$

$$-b(\beta_0 + \sum_{k=1}^{q} \alpha_k Y_{i,j-k} + \sum_{l=1}^{r} (\beta_{xl} x_{i,j-l+1} + \beta_{zl} Z_{i,j-l+1}) / a \phi + c(Y_{i-, j}, x_{i-, j}, Z_{i-, j}), \phi$$

$$- \sum_{l=1}^{r} (W_{i,j-l+1} - x_{i,j-l+1})^2 / 2 \sigma_u^2 - r \log (2\pi \sigma_u^2).$$

We immediately recognize that this conditional density still belongs to an exponential family and moreover, we find that the sufficient statistics for $x_{i,j-k+1}, k = 1, \ldots, r$ are

$$T_{i1}^{(j)} = \frac{\beta_{x1}}{a \phi} Y_{ij} + \frac{1}{\sigma_u^2} W_{ij}, \ T_{i2}^{(j)} = \frac{\beta_{x2}}{a \phi} Y_{ij} + \frac{1}{\sigma_u^2} W_{i,j-1}, \ldots, \ T_{ir}^{(j)} = \frac{\beta_{xr}}{a \phi} Y_{ij} + \frac{1}{\sigma_u^2} W_{i,j-r+1}.$$
where

\[ g \]

Therefore, the distribution of \( Y \) given \( Y_{i,-j} \), \((Z_{ij}, Z_{i,-j})\) and \((T_{i1}^{(j)}, ..., T_{ir}^{(j)})\) only depends on \( \phi, \beta_0, \alpha_k(k = 1, ..., q) \) and \( \beta_l = (\beta_{z1}, \beta_{z2})^T(l = 1, ..., r) \). We abbreviate this distribution as \( \tilde{f}(Y_{ij}|V_{ij}(\theta); \theta) \), where \( \theta \) consists of all the regression parameters and \( V_{ij}(\theta) \) denotes those sufficient statistics conditioned on. Under the special case when \( r = 1 \), \( \tilde{f}(Y_{ij}|V_{ij}(\theta); \theta) \) is the same as the conditional distribution of \( Y_{ij} \) given \( Y_{i,-j} \), \((Z_{ij}, Z_{i,-j})\) and \( T_{i1}^{(j)} \) only.

From the property

\[
E_{\theta_0} \left\{ \nabla_\theta \log \tilde{f}(Y_{ij}|V_{ij}(\theta_0); \theta) \bigg| \theta = \theta_0 \right\} = E_{\theta_0} \left\{ \nabla_\theta \log \tilde{f}(Y_{ij}|V_{ij}(\theta_0); \theta) \bigg| V_{ij}(\theta_0) \right\} \bigg| \theta = \theta_0 \right] = 0
\]

where \( \nabla_\theta \) denote the gradient with respect to \( \theta \), we can construct the following estimating equation

\[
\sum_{i=1}^{n} \sum_{j=(r-1)vq+1}^{m} g(Y_{ij}|v_{ij} = V_{ij}(\theta); \theta) = 0, \tag{11}
\]

where \( g(y_{ij}|v_{ij}; \theta) \) denotes the gradient of \( \tilde{f}(y_{ij}|v_{ij}; \theta) \) with respect to \( \theta \). Note that calculations of this gradient is done by viewing \( v_{ij} \) as fixed, not a function of \( \theta \) and then evaluating \( v_{ij} \) at \( v_{ij} = V_{ij}(\theta) \).

To distinguish (11) from the conditional score equation in Stefanski and Carroll (1987), we call our proposed estimating equation the \textit{pseudo conditional score equation}.

The Newton-Raphson iteration can be used to solve the equation. The following theorem gives the asymptotic property of any consistent solution to (11).

**THEOREM 2.** Let \( \theta_0 \) denote the true value of \( \theta \). Assume that with probability 1, in a neighborhood of \( \theta_0 \), \( \nabla_\theta g(Y_{ij}|V_{ij}(\theta); \theta) \) is Lipschitz continuous with respect to \( \theta \) and moreover,

\[
E_{\theta_0} \left\{ \nabla_\theta g(Y_{ij}|V_{ij}(\theta_0); \theta) \bigg| \theta = \theta_0 \right\} \text{ is non-singular.}
\]

Then there exists a solution, \( \hat{\theta}_n \), to equation (11) and \( \sqrt{n}(\hat{\theta}_n - \theta_0) \) converges in distribution to a normal distribution with mean zero and covariance

\[
\Sigma(\theta_0) = E_{\theta_0} \left\{ \sum_{j=(r-1)vq+1}^{m} \nabla_\theta g(Y_{ij}|V_{ij}(\theta); \theta) + \sum_{j=(r-1)vq+1}^{m} g(Y_{ij}|V_{ij}(\theta_0); \theta) \bigg| V_{ij}(\theta_0) \right\}^{-1} \\
\times E_{\theta_0} \left\{ \sum_{j=(r-1)vq+1}^{m} g(Y_{ij}|V_{ij}(\theta_0); \theta) \bigg| V_{ij}(\theta_0) \right\}^T \\
\times E_{\theta_0} \left\{ \sum_{j=(r-1)vq+1}^{m} \nabla_\theta g(Y_{ij}|V_{ij}(\theta); \theta) + \sum_{j=(r-1)vq+1}^{m} g(Y_{ij}|V_{ij}(\theta_0); \theta) \bigg| V_{ij}(\theta_0) \right\}^{-1}.
\]
The proof is given in Appendix. A consistent estimator for $\Sigma$ is

$$\hat{\Sigma}_n = n \left[ \sum_{i=1}^{n} \sum_{j=(r-1)\vee 1}^{m} \nabla g(Y_{ij} | V_{ij}(\theta); \theta)_{\theta=\hat{\theta}_n} \right]^{-1} \times \left[ \sum_{i=1}^{n} \left\{ \sum_{j=(r-1)\vee 1}^{m} g(Y_{ij} | V(\hat{\theta}_n); \hat{\theta}_n) \right\} \left\{ \sum_{j=(r-1)\vee 1}^{m} g(Y_{ij} | V(\hat{\theta}_n); \hat{\theta}_n) \right\}^{T} \right]^{-1} \times \left[ \sum_{i=1}^{n} \sum_{j=(r-1)\vee 1}^{m} \nabla g(Y_{ij} | V(\hat{\theta}_n); \theta)_{\theta=\hat{\theta}_n} \right].$$

4.2 Numerical studies

We apply our proposed method to two special examples. In the first example, we consider a linear transition model with $r = 1$ and $q = 1$. Then it is easy to calculate that for $j \geq 2$, $\hat{f}(Y_{ij} | V_{ij}(\theta); \theta)$, which is the conditional density of $Y_{ij}$ given $T_{1}^{(j)} = \beta_x Y_{ij} / \sigma_y^2 + W_{ij} / \sigma_u^2$ and $(Y_{i,j-1}, \ldots, Y_{i1})$ as well as $(Z_{ij}, \ldots, Z_{i1})$, is the same as the conditional density of $Y_{ij}$ given $Q_{ij} = \beta_x (Y_{ij} - \beta_0 - \alpha Y_{i,j-1} - \beta_z^T Z_{ij}) / \sigma_y^2 + W_{ij} / \sigma_u^2$ and $(Y_{i,j-1}, \ldots, Y_{i1})$ as well as $(Z_{ij}, \ldots, Z_{i1})$. Direct calculation gives that the logarithm of this conditional density is equal to

$$- \log \sqrt{2\pi \sigma_y^2} - (2\sigma_y^2)^{-1}(Y_{ij} - \beta_0 - \alpha Y_{i,j-1} - \beta_z^T Z_{ij} - Q_{ij}\beta_x^*)^2, \ j = 2, \ldots, m,$$

where $\beta_x^* = \beta_x / (\beta_x^2 / \sigma_y^2 + 1 / \sigma_u^2)$ and $\sigma_y^* = (\beta_x^2 / \sigma_y^2 + 1 / \sigma_u^2)^{-1}\sigma_y^2 / \sigma_u^2$. After differentiating with respect to all the parameters then substituting the expression of $Q_{ij}$, we obtain that the following pseudo-conditional-score equations

$$0 = \sum_{i=1}^{n} \sum_{j=2}^{m} \left( \frac{1}{Z_{ij}} \right) \left\{ Y_{ij} - \beta_0 - \alpha Y_{i,j-1} - \beta_z^T Z_{ij} - \beta_x W_{ij} \right\},$$

$$0 = \sum_{i=1}^{n} \sum_{j=2}^{m} \left\{ (Y_{ij} - \beta_0 - \alpha Y_{i,j-1} - \beta_z^T Z_{ij}) \beta_x + W_{ij} \sigma_y^2 / \sigma_u^2 \right\} \left( Y_{ij} - \beta_0 - \alpha Y_{i,j-1} - \beta_z^T Z_{ij} - \beta_x W_{ij} \right),$$

$$0 = \sum_{i=1}^{n} \sum_{j=2}^{m} \left\{ (Y_{ij} - \beta_0 - \alpha Y_{i,j-1} - \beta_z^T Z_{ij} - \beta_x W_{ij})^2 - (\beta_x^2 \sigma_u^2 + \sigma_y^2) \right\}.$$

In the second example, we consider a logistic transition model with $r = q = 1$, where $Y_{ij}$ is a Bernoulli variable and follows the logistic regression model. The likelihood function yields that the sufficient statistics for $x_{ij}$ is given by $T_{1}^{(j)} = \beta_x Y_{ij} + W_{ij} / \sigma_u$, for $j = 2, \ldots, m$. Thus, the logarithm of the conditional density $\hat{f}(Y_{ij} | T_{1}^{(j)}; \theta)$ is obtained as

$$- \frac{(T_{1}^{(j)} - Y_{ij} \beta_x)^2 \sigma_u^2}{2} + Y_{ij}(\beta_0 + \beta_z^T Z_{ij} + \alpha Y_{i,j-1})$$

10
\[-\log \left[ \exp \left\{ -\frac{(T_{ij}^{(j)} - \beta_x)^2 \sigma_u^2}{2} + (\beta_0 + \beta_x^T Z_{ij} + \alpha Y_{i,j-1}) \right\} + \exp \left\{ -\frac{T_{ij}^{(j)2} \sigma_u^2}{2} \right\} \right].\]

After differentiating the above function with respect to all the parameters then substituting the expression of $T_{ij}^{(j)}$, we obtain the following pseudo-conditional score equations

\[
0 = \sum_{i=1}^{n} \sum_{j=2}^{m} \left( \frac{1}{Y_{i,j-1} Z_{ij}} \right) \left[ Y_{ij} - \frac{1}{1 + \exp \left\{ (1/2 - Y_{ij}) \beta_x^2 \sigma_u^2 - \beta_x W_{ij} - (\beta_0 + \beta_x^T Z_{ij} + \alpha Y_{i,j-1}) \right\}} \right],
\]

\[
0 = \sum_{i=1}^{n} \sum_{j=2}^{m} \left[ Y_{ij} W_{ij} - \frac{(Y_{ij} \beta_x + W_{ij} \sigma_u^2 - \beta_x) \sigma_u^2}{1 + \exp \left\{ (1/2 - Y_{ij}) \beta_x^2 \sigma_u^2 - W_{ij} \beta_x - (\beta_0 + \beta_x^T Z_{ij} + \alpha Y_{i,j-1}) \right\}} \right].
\]

We implement these two set of equations in our simulation studies. Especially, in the first simulation, the longitudinal response $Y_{ij}$ is generated from

\[Y_{ij} = -1 + 0.4Y_{i,j-1} + 3X_{ij} + 0.8Z_i + N(0,1), \quad i = 1, \ldots, n, j = 2, \ldots, 5,\]

where $Z_i$ is a Bernoulli variable with $P(Z_i = 1) = 0.5$ and $X_{ij}$ follows another transition model

\[X_{ij} = 0.5 + 0.8X_{i,j-1} + N(0,1), \quad i = 1, \ldots, n, j = 2, \ldots, 5.\]

Moreover, we use $X_{i1} = 0.25$ and $Y_{i1} = -5/12 + 5Z_i/3$ as values at time one. The measurement error distribution in (3) has a variance 0.5. In the second simulation, we generate binary response from a logistic transition model with mean

\[E[Y_{ij} | H_{ij}] = \frac{\exp\{-1 + 0.5Y_{i,j-1} + X_{ij} + 0.8Z_{ij}\}}{1 + \exp\{-1 + 0.5Y_{i,j-1} + X_{ij} + 0.8Z_{ij}\}}, \quad i = 1, \ldots, n, j = 2, \ldots, 5,
\]

where $Z_i$ is generated from a Bernoulli distribution with $P(Z_i = 1) = 0.5$ and $X_{ij}$ follows

\[X_{ij} = 0.4 + 0.5Z_i + 0.6X_{i,j-1} + N(0,0.5) \quad i = 1, \ldots, n, j = 2, \ldots, 5.\]

The measure error has variance 0.5. In both simulations, we solve the pseudo-conditional score equations to derive the estimators and estimate the asymptotic variance using the formula $\hat{\Sigma}_n$. Table 1 reports the summary results from both simulation with sample sizes 100 or 200 after 1000 repetitions. Table 1 indicates that in small sample, the estimates have virtually no bias and the estimated standard errors agree well with the true standard errors.

In a third simulation study to examine the robustness of the proposed approach, we use the same setting as in the first simulation study except that $X$’s error distribution is a mixture of $N(-3,1)$ and $N(3,1)$ with mixing probability 0.5. We then estimate the regression parameters either using the pseudo-conditional score approach or using the “maximum likelihood approach” assuming a misspecified normal error for $X$. The simulation results from $n = 100$ and $n = 200$ based on 1000 repetitions.
are reported in Table 2. The table shows that the estimates from the pseudo-conditional score approach have bias as small as 1% of the true values while the “maximum likelihood approach” produces bias as large as 15% of the true values.

As an example, we apply our method to analyze the ACSUS data. Specifically, we restricted our attention to 533 who completed the first year interviews. These interviews occurred every 3 months. The outcome of interest is whether they had hospital admission (yes/no) during the four interviews. One interest is to estimate the risk of CD4 count on the hospitalization given the past history. Thus, a natural model for analyzing this data is via the transition model while accounting for the measurement error in the CD4 count. Particularly, a logistic transition model is used to fit the data with covariate $W = \log(CD4/100)$, a transformation that reduces the marked skewness of CD4 count, and other covariates including patient’s age category from 1 to 10, whether s/he used antiretroviral drug, whether s/he was HIV-symptomatic at the start of the study, patient’s race and gender. Additionally, the past hospitalization history is also adjusted for in the analysis. The size of the measurement error for $W$, $\sigma_w^2$, is set to be $1/3$ of the variance of baseline $W$ and it is equal to 0.38. This value is also close to the estimated value 0.39 by Wulfsohn and Tsiatis (1995) using data from a clinical trial conducted by Burroughs-Wellcome.

To determine the transition orders, we first note that the first order autocorrelations among $W$’s are all above 0.85; thus this suggests that only current CD4 count is sufficient to represent the previous CD4 history, i.e., $r = 1$. Since the total number of measurements per subject is 4, the maximal value of $q$ can only be 3. We then fit the data with $q = 3$ while treating the outcomes at the first three interviews as initial states. The result shows that the coefficients for the second and third order terms are highly nonsignificant. Hence, our final model has transition order $q = 1$. The fitted result is given in Table 3 and it shows that there exists significant difference between females and males and even after adjusting for the previous hospitalization status, the effect of CD4 on the risk of hospitalization is still significant. The patients who had previous hospital admission history and who had lower CD4 counts would be more likely to be hospitalized in the future. We also fit the model by letting $\sigma_w^2$ be 0.18 which responds to the coefficient of variation being 50% in the baseline $W$ and the findings as shown in Table 3 are similar.

5. SEMIPARAMETRIC EFFICIENT ESTIMATION

5.1. Asymptotic efficiency in pseudo conditional score estimation

The pseudo-conditional score equation approach relies on the conditional likelihood function, so
it does not utilize the full data information; as the results, it may not give the efficient estimators. Thus, it is useful to know how much efficiency is lost when using such an approach. Since deriving the asymptotic efficiency bound for model (2) is generally difficult, we focus our discussion on the situation that \( Y_{ij} \) is a Gaussian outcome and \( r = 1 \) and \( q = 1 \) in (2). Additionally, we assume \( \{ Z_{ij} \} \) and \( \{ X_{ij} \} \)'s are independent but we allow the repeated measures of \( X \) to be correlated and the repeated measures of \( Z \) to be correlated.

From the previous discussion, we have known that
\[
Q_{ij} = \beta_x(Y_{ij} - \alpha Y_{i,j-1} - \beta_z Z_{ij})/\sigma_y^2 + W_{ij}/\sigma_u^2, j = 2, ..., m
\]
are sufficient statistics for \( X_{ij}, j = 2, ..., m \). In fact, they are also complete sufficient statistics. Therefore, following Bickel et al. (1993, Chap 4, pp. 130), one can show that the efficient score function for \( \theta = (\beta_0, \beta_x, \alpha, \beta_z, \sigma_y^2) \) is equal to
\[
\hat{\ell}_\theta^*(Y_i, W_i, Z_i; \theta, G) = E[\hat{\ell}_\theta^*(Y_i, W_i, Z_i, X_i; \theta)|Y_i, W_i, Z_i] - E[\hat{\ell}_\theta^*(Y_i, W_i, Z_i, X_i; \theta)|Q_i, Z_i],
\]
where \( Y_i = (Y_{i2}, ..., Y_{im}), W_i = (W_{i2}, ..., W_{im}), Q_i = (Q_{i2}, ..., Q_{im}) \) and \( \hat{\ell}_\theta^* \) is the score function for \( \theta \) with the complete data \((Y, X, Z)\). Here, \( G(\cdot) \) denotes the joint distribution of \((X_{i2}, ..., X_{im})\). Specifically, we obtain
\[
\hat{\ell}_\theta^*(Y_i, W_i, Z_i; \theta, G) = \frac{1}{\sigma_y^2} \sum_{j=2}^{m} \left( \begin{array}{c}
Y_{ij-1} - E[Y_{ij-1} | Q_{ij}] \\
E[Y_{ij-1} | Q_{ij}]
\end{array} \right) - \beta_x(E[X_{ij} | Q_{ij}]) E[X_{ij} | Q_{ij}],
\]
where \( E[X_{ij} | Q_{ij}] = \int X_{ij | Q_i} g(Q_i | X_i, \theta) dG(X_i) \) and \( q(Q_i | X_i, \theta) \) is the conditional density of \( Q_i \) given \( X_i \), also given by
\[
q(Q_i | X_i, \theta) = \left\{ \left( \frac{1}{\sqrt{2\pi}} (\beta_x^2/\sigma_y^2 + 1/\sigma_u^2) \right)^{-m} \exp \left\{ -\frac{\sum_{j=2}^{m} (Q_{ij} - (\beta_x^2/\sigma_y^2 + 1/\sigma_u^2) X_{ij})^2}{2(\beta_x^2/\sigma_y^2 + 1/\sigma_u^2)} \right\} \right\}.
\]
It follows that the semiparametric efficiency bound is given by $\Sigma_e = \{E[\hat{l}_\theta^*(Y_i, W_i, Z_i; \theta, g)^2]\}^{-1}$. Then the efficiency loss in the pseudo-conditional score estimating equations can be evaluated by comparing $\Sigma_e$ with $\Sigma$, where $\Sigma$ is given in Theorem 1. Particularly, the explicit forms of $\Sigma_e$ and $\Sigma$ are given in Appendix A.2 when $X_i$ follows an AR(1) model.

We utilize a concrete example to illustrate the efficiency loss. Suppose that $(Y_i, W_i)$ follows
\[
Y_{ij} = -1 + 0.5Y_{i,j-1} + X_{ij} + 0.6Z_i + N(0, 2),
\]
\[
W_{ij} = X_{ij} + N(0, 0.5),
\]
where $Z_i$ is a Bernoulli variable with $P(Z_i = 1) = 0.5$ and $X$ is generated from the following transition model
\[
X_{ij} = 0.4 + 0.5X_{i,j-1} + N(0, \sigma_x^2).
\]
For different choices of $\sigma_x^2 = 0.3$ or 0.15 and different cluster size $m = 3$ or 4, we compute the asymptotic relative efficiency of the estimators for $x, z$ in the pseudo-conditional score approach and compared with the semiparametric efficient bound. The results are presented in Table 4. The results in Table 4 show that using the pseudo conditional score method, almost no efficiency is lost in estimating $z$; however, the efficiency loss in the estimators of $x$ and $\alpha$ varies for different choices of the cluster size and the error variation in $X$ and such a loss can be as large as 20% in some scenarios.

5.2. Semiparametric efficient estimation with validation data

When a set of validation data for $X$, say $\tilde{X}_1, ..., \tilde{X}_N$, is available, we propose a one-step estimator to improve efficiency by taking advantage of the explicit expression of the efficient score function for $\theta$. Especially, the new estimator for $\theta$ is given by
\[
\tilde{\theta}_n = \hat{\theta}_n + \left\{ \frac{1}{n} \sum_{i=1}^n \hat{l}_\theta(Y_i, W_i, Z_i; \hat{\theta}_n, \hat{G}_n) \right\}^{-1} \left\{ \frac{1}{n} \sum_{i=1}^n l_\theta(Y_i, W_i, Z_i; \hat{\theta}_n, \hat{G}_n) \right\},
\]
where $\hat{G}_n$ is the empirical distribution of $X$ from the validation set and $\hat{l}_\theta(\cdot)$ is the efficient score function given in (12). The following theorem shows that the one-step estimator $\tilde{\theta}_n$ from (13) attains the semiparametric efficiency bound and its asymptotic variance can be consistently estimated by
\[
\left\{ \frac{1}{n} \sum_{i=1}^n \hat{l}_\theta(Y_i, W_i, Z_i; \hat{\theta}_n, \hat{G}_n) \right\}^{-1}.
\]

**THEOREM 3.** Suppose $n, N \to \infty$. Then $\sqrt{n}(\tilde{\theta}_n - \theta_0)$ converges in distribution to a normal distribution with mean zero with variance equal to $E \left[ l_\theta^*(Y_i, W_i, Z_i; \theta_0, G_0) \right]^{-1}$, where $G_0$ is the true distribution of $X$. 

14
The proof of the theorem is given in Appendix. Particularly, when \( N/n \to 0 \), i.e., the information from the validation set is nuisance as compared to the full data information, then the semiparametric efficiency bound even with validation observations is still the same as 
\[
E[\hat{\ell}^o_0(Y_i, W_i, Z_i; \theta_0, G_0) \hat{g}^o_0(Y_i, W_i, Z_i; \theta_0, G_0)^T]^{-1}.
\]
Thus, Theorem 3 implies that when \( N/n \to 0 \), \( \tilde{\theta}_n \) attains the asymptotic efficiency bound.

We also conduct a simulation study to examine the performance of the one-step estimator. The simulation setting is the same as in the previous section and \( \sigma^2_x \) is chosen to be 0.3 and 0.15 and the cluster size \( m \) is 3 or 4. Moreover, we let \( X_{i1} = 0.8 \) and \( Y_{i1} = -0.4 + 2Z_i \). In order to compare the pseudo conditional score estimator and the one-step estimator, we generate \( N = n/4 \) observations of \( X_i = (X_{i1}, ..., X_{im}), i = 1, ..., N \). Our results from 1000 repetitions are summarized into Table 5. We observe that both the pseudo-conditional score estimate and the one-step estimate perform well in the sample size 200 and 400 and the corresponding inference is accurate. The variance for the estimate of \( \beta_x \) increases significantly when \( \sigma^2_x \) decreases from 0.3 to 0.15; however, the estimates for both \( \beta_x \) and \( \alpha \) do not change much. Efficiency is not gained with the one-step procedure for estimating \( \beta_x \), while efficiency is gained a very small fraction in estimating \( \alpha \). However, using the one-step estimate, the efficiency is gained in estimating \( \beta_x \) and such an efficiency gain vary from 5% to more than 20% when \( \sigma^2_x \) decreases from 0.30 to 0.15. Additionally, the more validation data are used or the smaller cluster each subject has, such an efficiency gain is more significant. Therefore, our simulation results comply with the previous theoretical calculations in Table 4, where we indicate that the one-step procedure does not improve the efficiency in estimating \( \beta_x \) and most improve the estimation for \( \beta_x \).

To understand why such an efficiency gain increases with the validation size \( N \) while decreases with the cluster size and the \( \sigma^2_x \), we recall that in the one-step procedure, it is necessary to obtain an empirical estimate for \( E[X_i|Q_i] \) using the validation data. Therefore, when the variance of \( X_i \) is smaller, the cluster size is smaller, or the validation size is larger, such an estimate will be more accurate in finite sample calculation then the one-step estimate’s efficiency gain will be more likely to be observed. This conclusion has also been confirmed by our other simulations not reported here, where when the size of the validation data is small and the \( \sigma^2_x \) is relatively large, we observe little efficiency gain using the one-step procedure.

6. DISCUSSION

We consider in this paper transition measurement error models for longitudinal data. We show that the maximum likelihood estimator is likely to be asymptotically biased when the distribution of the unobserved covariate is misspecified. We propose a pseudo conditional score approach that
does not require specifying the distribution of the unobserved covariate. We investigate the efficiency loss of such estimators and propose a semiparametric efficient one-step estimator when a small set of validation data is available. Both numerical calculations and simulation studies show that the estimators using the pseudo conditional score equations perform well and subject to small loss of efficiency. The one-step estimator using the validation data may improve the efficiency.

We acknowledge that the one-step efficient estimation relies on the explicit formulation of the semiparametric efficient score function. However, this formulation does not exist for more complicated model such as logistic transition models. One possible approach is to maximize the observed likelihood function, where the unknown distribution of $X$ is substituted with a discrete distribution on the observed validation observations. Such an approach generally requires a large size of validation data and computation can be expensive.

One important issue in fitting a transition model is the selection of transition orders of $r$ and $q$. Currently there does not exist any literature on choosing $r$ and $q$ in our current semiparametric setting. However, order selection has been discussed in detail via either Akaike information criteria or Bayesian information criteria for parametric structural models in Pan et al. (2006). Thus, we suggest practical users to first select transition orders using structural models then obtain robust estimates using our semiparametric method.

Another important issue is to determine the size of measurement error, $\sigma_u^2$. When neither validation set nor prior knowledge is available, one possible strategy is to conduct sensitivity analysis and report the estimates and their variations under a reasonable range of measurement error sizes. Such analysis can be useful in practice.

APPENDIX

Proof of Theorem 2

From the condition and the inverse mapping theorem, the map

$$\theta \mapsto n^{-1} \sum_{i=1}^{n} \sum_{j=(r-1)\bmod q+1}^{m} g(Y_{ij}|V_{ij}(\theta); \theta)$$

is invertible in a neighborhood of $\theta_0$. Since $n$ is large, 0 is in the image of the map, we conclude that there exists a solution $\hat{\theta}_n$ to equation (11). The asymptotic normality follows from Theorem 5.41 (van der Vaart, 1998).

Calculation of $\Sigma_e$ and $\Sigma$ in Section 5.1
To facilitate the calculation, we let $C_0 = \beta_x^2 \sigma_y^2 + \sigma_y^2$, $C_1 = \sigma_y^2 / \sigma_y^2 (\beta_x^2 / \sigma_y^2 + 1/\sigma_y^2)^{-1}$ and $C_2 = \beta_x (\beta_x^2 / \sigma_y^2 + 1/\sigma_y^2)^{-1}$. Also define $\Delta_{ij} = \bar{e}_{ij} - E[\bar{e}_{ij}|Q_i]$ and $\tau_{ij}(Q_i) = E[\bar{e}_{ij}|Q_i] - \beta_x E[X_{ij}|Q_i]$.

We first derive the expression of $\Sigma_e$. Using the new notation, we rewrite (12) as

$$
\hat{\delta}_g(Y_i, W_i, Z_i; \theta, \theta) = \frac{1}{\sigma_y^2} \begin{pmatrix}
\Delta_{i1} + \sum_{j=2}^{m-1} \Delta_{ij} + \Delta_{im} \\
Z_{i1} \Delta_{i1} + \sum_{j=2}^{m-1} Z_{ij} \Delta_{ij} + Z_{im} \Delta_{im} \\
A_1(Q_i) \Delta_{i1} + \sum_{j=2}^{m-1} A_j(Q_i) \Delta_{ij} + A_m(Q_i) \Delta_{im} + B(Q_i) + \sum_{j=2}^{m-1} \sum_{k=1}^{j-1} \alpha^{j-1-k} \Delta_{ik} \Delta_{ij} \\
E[X_{i1}|Q_i] \Delta_{i1} + \sum_{j=2}^{m-1} E[X_{ij}|Q_i] \Delta_{ij} + E[X_{im}|Q_i] \Delta_{im} \\
\frac{1}{\sigma_y^2} \tau_{11}(Q_i) \Delta_{i1} + \sum_{j=2}^{m-1} \frac{1}{\sigma_y^2} \tau_{ij}(Q_i) \Delta_{ij} + \frac{1}{\sigma_y^2} \tau_{im}(Q_i) \Delta_{im} - \frac{1}{2\sigma_y^2} \text{var}(\bar{e}_{ij}|Q_i) + \frac{1}{2\sigma_y^2} \sum_{j=2}^{m-1} \Delta_{ij}^2
\end{pmatrix}.
$$

where

$$
A_1(Q_i) = \sum_{k=2}^{m} \alpha^{k-1} \tau_{ik}(Q_i) + E[Y_{i0}|Q_i],
$$

$$
A_j(Q_i) = \sum_{k=1}^{j-1} \alpha^{j-1-k} \beta_x (Z_{ik} - E[Z_{ik}|Q_i]) + \sum_{k=j+1}^{m} \alpha^{k-1-j} \tau_{ik}(Q_i) + E[Y_{i,j-1}|Q_i],
$$

$$
A_m(Q_i) = \sum_{k=1}^{m-1} \alpha^{m-k-1} \tau_{ik}(Q_i) + E[Y_{i,m-1}|Q_i],
$$

$$
B(Q_i) = \sum_{j=2}^{m} \sum_{k=1}^{j-1} \alpha^{j-1-k} \beta_x (Z_{ik} - E[Z_{ik}|Q_i]) \tau_{ij}(Q_i).
$$

Using the fact that $\Delta_{i1}, ..., \Delta_{im}$ are conditionally independent given $Q_i$ and they follow normal distributions with mean zero and constant variance $C_1$, we obtain that $\Sigma_e$ is equal to the inverse of

$$
\begin{pmatrix}
\sigma_{33} & C_1 \sum_{j=2}^{m} E[Z_{ij}] & C_1 \sum_{j=2}^{m} E[Y_{i,j-1}] & C_1 \sum_{j=2}^{m} E[X_{ij}] \\
C_1 \sum_{j=2}^{m} E[Z_{ij}] & C_1 \sum_{j=2}^{m} E[Z_{ij}^2] & C_1 \sum_{j=2}^{m} E[Y_{i,j-1}Z_{ij}] & C_1 \sum_{j=2}^{m} E[X_{ij}Z_{ij}] \\
C_1 \sum_{j=2}^{m} E[Y_{i,j-1}]C_1 \sum_{j=2}^{m} E[Z_{ij}] & C_1 \sum_{j=2}^{m} E[Y_{i,j-1}Z_{ij}] & C_1 \sum_{j=2}^{m} E[Y_{i,j-1}^2] & C_1 \sum_{j=2}^{m} E[Y_{i,j-1}X_{ij}] \\
0 & C_1 \sum_{j=2}^{m} E[X_{ij}] & C_1 \sum_{j=2}^{m} E[X_{ij}Z_{ij}] & \sigma_{44} & \sigma_{45} & \sigma_{45} & \sigma_{45} & \sigma_{45}
\end{pmatrix} / \sigma_y^4,
$$

where

$$
\sigma_{33} = \sum_{j=2}^{m} \sum_{k=1}^{j-1} \alpha^{j-1-k} C_1^2 + E[A_1(Q_i)^2]C_1 + \sum_{j=2}^{m-1} E[A_j(Q_i)^2]C_1 + E[A_m(Q_i)^2]C_1 + E[B(Q_i)^2];
$$

$$
\sigma_{34} = E[A_1(Q_i)E[X_{i1}|Q_i]]C_1 + \sum_{j=2}^{m-1} E[A_j(Q_i)E[X_{ij}|Q_i]]C_1 + E[A_m(Q_i)E[X_{im}|Q_i]]C_1;
$$

$$
\sigma_{35} = \frac{1}{\sigma_y^2} E[A_1(Q_i)\tau_{11}(Q_i)]C_1 + \sum_{j=2}^{m-1} E[A_j(Q_i)\tau_{ij}(Q_i)]C_1 + E[A_m(Q_i)\tau_{im}(Q_i)]C_1;
$$

$$
\sigma_{44} = \sum_{j=2}^{m} E[E[X_{ij}|Q_i]^2]C_1;
$$

17

http://biostats.bepress.com/harvardbiostat/paper32
\[ \sigma_{45} = \frac{1}{\sigma_y^2} \sum_{j=2}^{m} E[E[X_{ij} | Q_i] \tau_{ij}(Q_i)] C_1; \]
\[ \sigma_{55} = \frac{1}{4\sigma_y^4} (2nC_i^2 + 4 \sum_{j=2}^{m} E[\tau_{ij}(Q_i)^2] C_1). \]

To derive the expression of \( \Sigma \), the asymptotic covariance matrix for the pseudo-conditional score estimator, we note that from Theorem 1, \( \Sigma \) is given by
\[ \hat{\Sigma} = \hat{\Sigma}_2^{-1} \hat{\Sigma}_1 (\hat{\Sigma}_2^{-1})^T, \]
in which
\[ \hat{\Sigma}_2 = \sum_{j=2}^{m} \begin{pmatrix} \frac{1}{\sigma_y^2} E[Z_{ij}] & E[Y_{ij-1}] & E[X_{ij}] & 0 \\ E[Z_{ij}] & E[Z_{ij}^2] & E[Y_{ij-1}] & E[X_{ij}] \\ E[Y_{ij-1}] & E[Y_{ij-1}Z_{ij}] & E[Y_{ij-1}^2] & E[Y_{ij-1}X_{ij}] \\ 0 & E[Y_{ij-1}Z_{ij}] & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \quad (A.2) \]
and
\[ \hat{\Sigma}_1 = C_0 \sum_{j=2}^{m} \begin{pmatrix} \frac{1}{\sigma_y^2} E[X_{ij}] & E[Y_{ij-1}] & E[X_{ij}] & 0 \\ E[Z_{ij}] & E[Z_{ij}^2] & E[Y_{ij-1}] & E[X_{ij}] \\ E[Y_{ij-1}] & E[Y_{ij-1}Z_{ij}] & E[Y_{ij-1}^2] & E[Y_{ij-1}X_{ij}] \\ 0 & E[Y_{ij-1}Z_{ij}] & 0 & 0 \\ 0 & 0 & 0 & 2C_0 \end{pmatrix}. \quad (A.3) \]

We can evaluate each term in the above expressions of (A.1), (A.2), and (A.3) when assuming

(M.1) \( (Y_i, W_i) \) follows \( Y_{ij} = \beta_0 + \beta_z Z_{ij} + \beta X_{ij} + \alpha Y_{i,j-1} + \epsilon_{ij}, W_{ij} = X_{ij} + U_{ij}; \)

(M.2) \( X \) is generated from the transition model \( X_{ij} = \gamma_0 + \gamma_x X_{i,j-1} + \epsilon_{xij}; \)

(M.3) \( Z_{ij} = \ldots = Z_{i1} \) has mean \( m_z \) and variance \( v_z \) and it is independent of \( X \);

(M.4) \( Y_0 \) has mean \( m_y \) and variance \( v_y \) and \( X_0 \) has mean \( m_x \) and variance \( v_x \);

(M.5) \( (\epsilon_{ij}, U_{ij}, \epsilon_{xij}) \) are independently from normal distribution with mean zero and variance \( \sigma_y^2, \sigma_u^2, \sigma_x^2 \) respectively.

For example, in calculating \( \sigma_{kl} \) in the matrix (A.1), we need calculate \( E[X_i | Q_i] \). We first notice that the joint density of \( (Q_i, X_i) \) is proportional to
\[ \exp\left\{ -\left( \frac{(Q - (\beta_0^2/\sigma_y^2 + 1/\sigma_y^2)X_i)T(Q_i - (\beta_0^2/\sigma_y^2 + 1/\sigma_y^2)X_i)}{2(\beta_0^2/\sigma_y^2 + 1/\sigma_y^2)} - \frac{(X_i - \mu_x)^T \Sigma_x^{-1} (X_i - \mu_x)}{2} \right) \right\}, \]
where \( \mu_x = (E[X_{i1}], \ldots, E[X_{im}])' \) and \( \Sigma_x \) is the covariance matrix of \( X_i \), i.e., its \( (k,l) \)-element is equal to \( E[X_{ik}X_{il}] - E[X_{ik}]E[X_{il}] \) for \( 1 \leq k, l \leq m \). Hence, \( X_i \) given \( Q_i \) is a multivariate-normal distribution with mean \( E[X_i | Q_i] = \Sigma_x^{-1} + (\beta_0^2/\sigma_y^2 + 1/\sigma_y^2)I_{m \times m}^{-1}(\Sigma_x^{-1} \mu_x + Q_i) \). Moreover, since \( E[\epsilon_{ij} | Q_i] = C_0 Q_{ik} \) and \( E[Y_{ij-1} | Q_i] = \Sigma_{ij-1} \alpha^{j-1-k}(\beta_0 + \beta_z m_z + C_2 Q_{ik}) + \alpha_j m_y \), each term in the expression of \( \sigma_{33}, \sigma_{34}, \sigma_{35}, \sigma_{44}, \sigma_{45} \) and \( \sigma_{55} \) is simply the expectation of a quadratic function of \( Q_i \).

Thus, \( \Sigma_e \) can be calculated from the additional facts that
\[ Q_i \sim \text{Multinormal}((\beta_0^2/\sigma_y^2 + 1/\sigma_y^2)E[X_i], (\beta_0^2/\sigma_y^2 + 1/\sigma_y^2)I_{m \times m} + (\beta_0^2/\sigma_y^2 + 1/\sigma_y^2)^2 \text{Cov}(X_i)) \]
and that

\[
E[X_{ij}] = \gamma_x^j m_x + \gamma_0 \frac{1 - \gamma_j^2}{1 - \gamma_x} + m_x \gamma_x \frac{1 - \gamma_j^2}{1 - \gamma_x},
\]

\[
E[X_{ij}X_{ik}] = E[X_{ij}]E[X_{ik}] + \sigma_x^2 \gamma_x^j \gamma_x^{k-1} \frac{1 - \gamma_x}{1 - \gamma_x^2} + \gamma_x \gamma_x \gamma_x^j (\frac{1 - \gamma_x^k}{1 - \gamma_x})^2, \quad k \leq j,
\]

\[
E[Y_{ij}] = \alpha^j m_y + \beta_0 \frac{1 - \alpha^j}{1 - \alpha} + m_x \beta_x \frac{1 - \alpha^j}{1 - \alpha} + \beta_x \sum_{k=1}^j \alpha^j \gamma_x^k E[X_{ik}],
\]

\[
E[Y_{ij}^2] = E[Y_{ij}]^2 + v_x \gamma_x^2 (\frac{1 - \alpha^j}{1 - \alpha})^2 + \alpha^j \gamma_x \gamma_x \gamma_x \gamma_x^j (\frac{1 - \alpha^2}{1 - \alpha^2})
\]
\[+ \sum_{k=1}^j \sum_{k'=1}^j \alpha^j \gamma_x^k \alpha^j \gamma_x^k (E[X_{ik}X_{ik'}] - E[X_{ik}]E[X_{ik'}]),
\]

\[
E[X_{ij}Y_{ij-1}] = E[X_{ij}] (\beta_0 \frac{1 - \alpha^{j-1}}{1 - \alpha} + \beta_x m_x \frac{1 - \alpha^{j-1}}{1 - \alpha} + m_y \alpha^{j-1})
\]
\[+ \sum_{k=1}^{j-1} \beta_x \alpha^j \gamma_x^k E[X_{ij}X_{ik}], \quad j \geq 2.
\]

Similarly, \( \Sigma \) can be calculated using the above equalities.

**Proof of Theorem 3**

We prove the same results under an even more general setting: Suppose that \( n \) i.i.d observations, \( O_1, ..., O_n \) are available but \( X_1, ..., X_n \) are missing. Moreover, the following assumptions hold:

(C.1) The conditional density of \( O \) given \( X \) is given by \( f(O|X; \theta) \) and \( X \) has a density \( g(X) \); moreover, \( f(O|X; \theta) \) are continuously twice differentiable with respect \( \theta \);

(C.2) \( Q \) is a function of \( O \) and \( \theta \) and in addition, \( Q \) is sufficient statistics for \( x \) in the family \( \{f(O|x; \theta)\} \) indexed by both \( x \) and \( \theta \);

(C.3) \( Q \) is also a complete statistics for \( x \) in the above family; that is, if \( E[w(Q)|X] = 0, a.s., \) then \( w(Q) = 0, a.s. \)

(C.4) there exists a consistent estimator \( \hat{\theta}_n \) such that \( |\hat{\theta}_n - \theta_0| = O_p(n^{-1/2}) \);

(C.5) the distribution of \( X \) is estimated by \( \hat{G}_n(x) \) and for some metric \( \rho \) and some function \( G^*(x) \), \( \rho(\hat{G}_n, G^*) \to 0 \) in probability.

From (C.1)-(C.5), using the result in Page 130-131 (BKRW, 1993), we immediately obtain that the efficient score function for \( \theta \) is given by

\[
i_{\bar{\theta}}^O(O; \theta; G) = E[i\bar{\theta}(O, X; \theta)|O] - E[i\bar{\theta}(O, X; \theta)|Q],
\]

(A.4)

where the subscript \( \theta \) means the derivative with respect to \( \theta \) and \( i\bar{\theta}(O, X; \theta) = \nabla_\theta \log f(O, X; \theta) \).
Therefore, the efficient influence function for $\theta$ is given by

$$\tilde{I}_\theta(O; \theta, G) = -\{E[i_{\theta\theta}(O; \theta, G)]\}^{-1}i_{\theta\theta}(O; \theta, G) = \{E[i_{\theta}(O; \theta, G)^{\otimes 2}]\}^{-1}i_{\theta}(O; \theta, G),$$

where $i_{\theta\theta}(O; \theta, G)$ is the derivative of $i_{\theta}(O; \theta, G)$ with respect to $\theta$.

Following the description in Section 5.2, a one-step estimator is constructed as follows:

$$\tilde{\theta}_n = \tilde{\theta}_n - \left\{\frac{1}{n} \sum_{i=1}^{n} i_{\theta\theta}(O; \tilde{\theta}_n, \tilde{G}_n)\right\}^{-1} \left\{\frac{1}{n} \sum_{i=1}^{n} i_{\theta}(O; \tilde{\theta}_n, \tilde{G}_n)\right\}.$$

Then the following property holds for this one-step estimator $\tilde{\theta}_n$.

**THEOREM A.1.** Let $(\theta_0, G_0)$ denote the true parameters and denote $E_{\theta,G}[w(O)]$ as the expectation of $w(O)$ when the parameters are $(\theta, G)$. In addition to (C.1)-(C.5), we suppose the following smoothness assumptions are also satisfied:

(C.6). $\{i_{\theta\theta}(O; \theta, G) : |\theta - \theta_0| < \delta_0, \rho(G, G^*) < \delta_0\}$ is a Donsker class for a small $\delta_0$, where $\rho$ is a semi-metric defined for $g$.

(C.7). $E_{\theta_0,G_0}[i_{\theta\theta}(O; \theta, G)]$ is continuous in $(\theta_0, G^*)$.

(C.8). $E_{\theta_0,G_0}[i_{\theta\theta}(O; \theta_0, G^*)]$ is a non-singular matrix.

Then $\sqrt{n}(\tilde{\theta}_n - \theta_0)$ weakly converges to a multivariate normal distribution with mean zero and covariance

$$\Sigma = \{E[i_{\theta\theta}(O; \theta_0, G^*)]\}^{-1}E[i_{\theta\theta}(O; \theta_0, G^*)]E[i_{\theta\theta}(O; \theta_0, G^*)]^{-1}.$$

Furthermore, if $G^*(x) = G_0(x)$, then $\tilde{\theta}$ is an efficient estimator for $\theta$; i.e., $\Sigma$ is equal to the semiparametric efficiency bound.

**PROOF.** We use the notation $P_n w(O) = \frac{1}{n} \sum_{i=1}^{n} w(O_i)$ and $P w(O) = E_{\theta_0,G_0}[w(O)]$.

$$\sqrt{n}(\tilde{\theta}_n - \theta_0)$$

$$= \sqrt{n}(\tilde{\theta}_n - \theta_0) + \sqrt{n}(P_n - P)\tilde{I}_\theta(O; \tilde{\theta}_n, \tilde{G}_n) + \sqrt{n}P\tilde{I}_\theta(O; \tilde{\theta}_n, \tilde{G}_n)$$

$$= \sqrt{n}(\tilde{\theta}_n - \theta_0) + \sqrt{n}(P_n - P)\tilde{I}_\theta(O; \tilde{\theta}_n, \tilde{G}_n)$$

$$- \sqrt{n}\{E[i_{\theta\theta}(O; \tilde{\theta}_n, \tilde{G}_n)]\}^{-1}P\tilde{I}_\theta(O; \tilde{\theta}_n, \tilde{G}_n).$$

(A.5)

By the assumption (C.6) and the Donsker theorem,

$$\sqrt{n}(P_n - P)\tilde{I}_\theta(O; \tilde{\theta}_n, \tilde{G}_n) = \sqrt{n}(P_n - P)\tilde{I}_\theta(O; \theta_0, G^*) + o_p(1).$$

(A.6)

Moreover, since the density of $O$ given $Q$ is independent of $X$, $E_{\theta_0,G_0}[Q(O)|T] = E_{\theta_0,G}[Q(O)|T]$ for any integrable function $Q(O)$. Therefore,

$$P\tilde{I}_\theta(O; \theta_0, G) = E_{\theta_0,G_0}[E_{\theta_0,G}[i_{\theta}(O, X; \theta)|O] - E_{\theta_0,G}[i_{\theta}(O, X; \theta)|Q]]$$
In other words, no matter what $G$ is, $\mathbf{P}^*_g(O; \theta_0, G)$ is always zero. Hence,

$$\mathbf{P}^*_g(O; \hat{\theta}_n, \hat{G}_n) = \mathbf{P}[\hat{\theta}_n(\hat{\theta}_n, \hat{G}_n) - \hat{\theta}_n(O; \theta_0, \hat{G}_n)] = \mathbf{P}[\hat{\theta}_n(\hat{\theta}_n, \hat{G}_n)|(\hat{\theta}_n - \theta_0) + o_p(\frac{1}{\sqrt{n}})]. \quad (A.7)$$

From (A.5), (A.6) and (A.7), we obtain that $\sqrt{n}(\hat{\theta}_n - \theta_0) = \sqrt{n}(P_n - \mathbf{P}) \hat{\theta}_n(O; \theta_0, G^*) + o_p(1)$.

The first conclusion follows. The second conclusion is clear since when $G^* = G_0$, $\hat{\theta}_n(O; \theta_0, G^*)$ is the efficient influence function.

REMARK A.1. One consistent estimate for the asymptotic covariance $\Sigma$ is

$$\left\{ \frac{1}{n} \sum_{i=1}^{n} \hat{\theta}_n(O; \tilde{\theta}_n, \tilde{G}_n) \right\}^{-1} \left\{ \frac{1}{n} \sum_{i=1}^{n} \hat{\theta}_n(O; \tilde{\theta}_n, \tilde{G}_n)^T \hat{\theta}_n(O; \tilde{\theta}_n, \tilde{G}_n) \right\} \times \left\{ \frac{1}{n} \sum_{i=1}^{n} \hat{\theta}_n(O; \tilde{\theta}_n, \tilde{G}_n) \right\}^{-1}.$$

REMARK A.2. In Theorem A.1, if $G^* = G_0$, i.e., $\hat{G}_n$ is consistent, one-step estimator can be generated using an alternative equation

$$\hat{\theta}_n = \hat{\theta}_n + \left\{ \frac{1}{n} \sum_{i=1}^{n} \hat{\theta}_n(O; \tilde{\theta}_n, \tilde{G}_n) \hat{\theta}_n(O; \tilde{\theta}_n, \tilde{G}_n)^T \right\}^{-1} \left\{ \frac{1}{n} \sum_{i=1}^{n} \hat{\theta}_n(O; \tilde{\theta}_n, \tilde{G}_n) \right\}.$$

Following the same arguments in proving Theorem A.1, we can easily show $\hat{\theta}_n$ is semiparametric efficient.

REMARK A.3. In the application of Theorem A.1 to a linear transition model with validation data of $X$, we take $\tilde{G}_n$ as the empirical distribution induced by the validation data and the metric $\rho$ is given by the weak convergence of the probability measures.

Figure 1: Histogram of the log-transformed CD4 count in the ACSUS data

Figure 2: Asymptotic Relative Biases in independent “MLEs” of $\beta_x$ and $\alpha$ in the Linear Transition Models for Gaussian Outcome, when AR(1) model for $X$ is true. The true parameter values are $\beta_0 = -1, \beta_x = 1, \alpha = 0.5, \sigma^2_x = 1$, and $\gamma_0 = 0.4, \gamma_x = 0.6, \sigma^2_x = 0.5$. The two plots correspond to (a) asymptotic relative bias in $\beta_{x,\text{indep}}$; (b) asymptotic relative bias in $\alpha_{\text{indep}}$.

Figure 3: Asymptotic Relative Biases in the independent “MLEs” of $\beta_x$ and $\alpha$ in the Generalized Linear Transition Models for non-Gaussian Outcome, when AR(1) model for $X$ is true. The true parameter values are $\beta_0 = -1, \beta_x = 1, \alpha = 0.5$, and $\gamma_0 = 0.4, \gamma_x = 0.6, \sigma_x^2 = 0.5$. The two plots correspond to (a) asymptotic relative bias in $\beta_{x,\text{indep}}$; (b) asymptotic relative bias in $\alpha_{\text{indep}}$.
