Attributing effects to interactions

Tyler J. VanderWeele and Eric J. Tchetgen Tchetgen

Abstract

A framework is presented which allows an investigator to estimate the portion of the effect of one exposure that is attributable to an interaction with a second exposure. We show that when the two exposures are independent, the total effect of one exposure can be decomposed into a conditional effect of that exposure and a component due to interaction. The decomposition applies on difference or ratio scales. We discuss how the components can be estimated using standard regression models, and how these components can be used to evaluate the proportion of the total effect of the primary exposure attributable to the interaction with the second exposure. In the setting in which one of the exposures affects the other, so that the two are no longer independent, alternative decompositions are discussed. The various decompositions are illustrated with an example in genetic epidemiology.

Introduction

In some settings it may be thought that the effect of a particular exposure is substantially altered in the presence or absence of a second exposure, so that some form of interaction exists between these two exposures^{1,2}. In such cases, it may be of interest to determine the extent to which the overall effect of the primary exposure of interest is due to the presence of the secondary exposure, and the primary exposure's interaction with it. In this paper we present an analytic framework within which to address such questions. We show that, if the two exposures are independent (uncorrelated) in the population then the overall effect of the primary exposure can be decomposed into two components, the first being the effect of the primary exposure when the secondary exposure is removed, and the second being a component due to interaction. We show how this decomposition applies on an additive scale, and on a risk ratio scale, and how regression models can be used to estimate each of the components. We discuss extensions to settings in which the two exposures are not independent but when one affects the other, and we also discuss a decomposition of joint effects of both exposures. The decompositions are illustrated with an various example from genetic epidemiology. We begin with introducing notation. We will keep both the notation and the setting relatively simple in the paper but consider more complex settings in the Appendix.

Definitions and Notation

We will let G and E denote two exposures of interest. These may be genetic and environmental exposures respectively but they could also both be genetic, or both environmental, or one or both could be behavioral. We will, for simplicity in exposition, refer to the first as a genetic exposure and the second as an environmental exposure, but again in principle the two exposures could be anything. When the ordering of the exposures is relevant we will assume that G precedes E . We will assume for simplicity that both exposures are binary; however we consider more general settings in the appendix.

Let Y be an outcome of interest that may be binary or continuous. When the outcome is binary we will use $p_g = P(Y = 1|G = g)$ to denote the probability of the outcome conditional on only $G = g$ and will use $p_e = P(Y = 1|E = e)$ to denote probability of the outcome conditional on only $E = e$. If the effect of G on Y is unconfounded then $p_{g=1} - p_{g=0} = P(Y = 1|G = 1) - P(Y = 1|G = 0)$ would equal to the effect of G on Y . If the effect of E on Y is unconfounded then $p_{e=1} - p_{e=0} = P(Y = 1|E = 1) - P(Y = 1|E = 0)$ would equal to the effect of E on Y . For simplicity, we will assume that there is no confounding for the effects of G and E on Y , but in the appendix we consider analogous results when the effects are unconfounded only conditional on some set of covariates C .

With a binary outcome we will also use $p_{ge} = P(Y = 1|G = g, E = e)$ to denote the probability of the outcome when $G = g$ and $E = e$. The standard interaction contrast on the additive scale would be written as $(p_{11} - p_{10} - p_{01} + p_{00})$ and assesses the extent to which the effect of both exposures together exceeds the effect of each considered separately.

Attributing Total Effects to Interactions Under Independence

Suppose now that the two exposures G and E are independent (uncorrelated) in the population and suppose that the effects of G and E on Y are unconfounded. We show in the Appendix that:

$$(p_{e=1} - p_{e=0}) = (p_{01} - p_{00}) + (p_{11} - p_{10} - p_{01} + p_{00})P(G = 1).$$

In other words, we can decompose the overall effect of E on Y into two pieces. The first piece is the conditional effect of E on Y when $G = 0$, the second piece is the standard additive interaction, $(p_{11} - p_{10} - p_{01} + p_{00})$, multiplied by the probability that $G = 1$. In some sense then we can attribute the total effect of E on Y to the part that would be present still if G were 0 (this is $p_{01} - p_{00}$), and to a part that has to do with the interaction between G and E (this is $(p_{11} - p_{10} - p_{01} + p_{00})P(G = 1)$). If we could remove the genetic exposure, i.e. set it to 0, we would remove the part that is due to the interaction and would be left with only $p_{01} - p_{00}$.

Since we can do this decomposition we might define a quantity $pAI_{G=0}(E)$ as the proportion of the overall effect of E that is attributable to interaction, with a reference category for the genetic exposure of $G = 0$, as

$$pAI_{G=0}(E) = \frac{(p_{11} - p_{10} - p_{01} + p_{00})P(G = 1)}{(p_{e=1} - p_{e=0})}.$$

The remaining portion $(p_{01} - p_{00})/(p_{e=1} - p_{e=0})$ is the proportion of the effect of E that would remain if G were fixed to 0. The proportion attributable to interaction could then be interpreted as the proportion of the effect of E we would eliminate if we fixed G to 0.

If Y is continuous, again assuming that G and E are uncorrelated, we have a similar decomposition, $E[Y|E = 1] - E[Y|E = 0] =$

$$\begin{aligned} & E[Y|G = 0, E = 1] - E[Y|G = 0, E = 0] \\ & + \{E[Y|G = 1, E = 1] - E[Y|G = 1, E = 0] - E[Y|G = 0, E = 1] + E[Y|G = 0, E = 0]\}P(G = 1) \end{aligned}$$

and we could likewise define the proportion attributable to interaction by: $pAI_{G=0}(E) =$

$$\frac{\{E[Y|G = 1, E = 1] - E[Y|G = 1, E = 0] - E[Y|G = 0, E = 1] + E[Y|G = 0, E = 0]\}P(G = 1)}{E[Y|E = 1] - E[Y|E = 0]}.$$

The two components of the decomposition, the portion due to interaction and the portion due to the effect of E when G is fixed to 0, also have a very intuitive form within a regression framework.

Consider the following regression model in which Y might be binary or continuous:

$$E[Y|G = g, E = e] = \alpha_0 + \alpha_1 g + \alpha_2 e + \alpha_3 eg. \quad (1)$$

We show in the appendix that irrespective of whether the outcome is binary or continuous, if G and E are independent, then the total effect of E on Y is given by $\alpha_2 + \alpha_3 P(G = 1)$, the portion due to interaction is equal to $\alpha_3 P(G = 1)$, and the portion due to the effect when G is fixed to 0 is equal to α_2 . Thus the proportion due to interaction is simply

$$pAI_{G=0}(E) = \frac{\alpha_3 P(G = 1)}{\alpha_2 + \alpha_3 P(G = 1)}.$$

Expressed in terms of regression coefficients, the decomposition seems almost obvious. The portion due to the effect when G is fixed to 0 is simply the main effect of E in the regression model, α_2 . The portion due to interaction is just the product coefficient α_3 multiplied by the probability that $G = 1$.

Although the decomposition in this form certainly seems obvious, we nevertheless believe this approach is in some sense novel. We believe this because (i) although obvious, we have

not seen this approach explicitly used; (ii) as illustrated in an example below the implications are in fact sometimes more subtle than they first appear, and finally (iii) the approach we have been considering thus far has assumed that the two exposures G and E are independent. As we will see later in the paper, the decomposition becomes somewhat more complicated when G and E are no longer independent in the population.

Note that under the assumption that G and E are independent, the roles of G and E can essentially be interchanged. Thus with a binary outcome we could likewise decompose the total effect of G on Y by: $(p_{g=1} - p_{g=0}) = (p_{10} - p_{00}) + (p_{11} - p_{10} - p_{01} + p_{00})P(E = 1)$. We could define the proportion of the effect of G that is attributable to interaction (with a reference category for E of $E = 0$) as $pAI_{E=0}(G) = \frac{(p_{11} - p_{10} - p_{01} + p_{00})P(E=1)}{(p_{g=1} - p_{g=0})}$. Expressed in terms of the coefficients of the regression model in (1) we have $pAI_{E=0}(G) = \frac{\alpha_3 P(E=1)}{\alpha_1 + \alpha_3 P(E=1)}$.

In the following section, we will consider how a similar decomposition of a total effect into a conditional effect and an interaction component can be done on a ratio scale and in the section after that we will discuss corresponding results when G and E are no longer independent. However, before we move on, we would like to illustrate some of the slightly more subtle implications of the decomposition above by way of a simple numerical example.

Suppose that G is a relatively rare genetic variant with prevalence $P(G = 1) = 0.01$ and that E is a somewhat more common environmental exposure with prevalence $P(E = 1) = 0.30$. Suppose that if we fit the linear risk model in (1) to the data we obtained:

$$E[Y|G = g, E = e] = (0.07) + (0.10)g + (0.02)e + (0.20)eg.$$

Here E has a relatively small main effect, only 0.02, and G has a considerably larger main effect, 0.10. We might then think, based on the regression model alone, that the proportion of the effect of E attributable to interaction would be larger than the proportion of the effect of G attributable to interaction, since the main effect of E is so small. However, if we calculate the proportion of the effect of G attributable to interaction we obtain

$$pAI_{E=0}(G) = \frac{\alpha_3 P(E = 1)}{\alpha_1 + \alpha_3 P(E = 1)} = \frac{(0.20)(0.30)}{(0.10) + (0.20)(0.30)} = 37.5\%.$$

If we calculate the proportion of the effect of E attributable to interaction we obtain

$$pAI_{G=0}(E) = \frac{\alpha_3 P(G = 1)}{\alpha_2 + \alpha_3 P(G = 1)} = \frac{(0.20)(0.01)}{(0.02) + (0.20)(0.01)} = 9.1\%.$$

In fact, a much smaller part of the effect of E , than of G , is attributable to interaction, even though the main effect of E is so small $\alpha_2 = 0.02$. This is because the proportion attributable to interaction for an exposure depends not only on the main effect of that exposure and the magnitude of the interaction, but also on the prevalence of the other exposure. The prevalence of the other exposure essentially determines how often the interaction will be in effect. Although the main effect for E is quite small, the prevalence of G is very low, $P(G = 1) = 0.01$, and so the interaction constitutes a relatively small proportion of the overall effect of E on the outcome.

Attributing Total Effects to Interactions on the Ratio Scale

Often, when an outcome is binary, a ratio scale is used to measure effects. We would define the relative risk for G as $RR_{g=1} = \frac{p_{g=1}}{p_{g=0}} = \frac{P(Y=1|G=1)}{P(Y=1|G=0)}$. Likewise we would define

the relative risk for E by $RR_{e=1} = \frac{p_{e=1}}{p_{e=0}} = \frac{P(Y=1|E=1)}{P(Y=1|E=0)}$. We can also define relative risks when G and E are considered together; we would define the relative risk for the outcome Y , comparing $G = g, E = e$ to the reference category $G = 0, E = 0$, as $RR_{ge} = \frac{p_{ge}}{p_{00}} = \frac{P(Y=1|G=g, E=e)}{P(Y=1|G=0, E=0)}$.

It is shown in the Appendix that if G and E are independent then we have the decomposition of the excess relative risk for E as:

$$(RR_{e=1} - 1) = \kappa(RR_{01} - 1) + \kappa(RR_{11} - RR_{10} - RR_{01} + 1)P(G = 1).$$

where κ is a scaling factor given by $\kappa = \frac{p_{00}}{p_{e=0}}$. As on the difference scale, so also on the ratio scale, we can decompose the excess relative risk for E , into two components: the first component is the excess relative risk for E if G were fixed to 0, $(RR_{01} - 1)$, and the second component is a portion of the effect due to interaction, $(RR_{11} - RR_{10} - RR_{01} + 1)P(G = 1)$. The contrast, $RR_{11} - RR_{10} - RR_{01} + 1$, is sometimes referred to as the 'relative excess risk due to interaction' or 'RERI'³ or the 'interaction contrast ratio'². We can thus re-express the decomposition above as

$$(RR_{e=1} - 1) = \kappa(RR_{01} - 1) + \kappa(RERI)P(G = 1).$$

Because of the scaling factor κ it does not necessarily make sense to estimate the specific portions, $\kappa(RR_{01} - 1)$, and $\kappa(RERI)P(G = 1)$, of the total effect, but if we consider the proportion of the effect of E attributable to interaction, then the scaling factor κ drops out and we obtain:

$$pAI_{G=0}(E) = \frac{(RERI)P(G = 1)}{(RR_{01} - 1) + (RERI)P(G = 1)}.$$

By symmetry a similar decomposition holds for the overall effect of G on Y on the risk ratio scale and we have the proportion of the effect of G attributable to interaction is

$$pAI_{E=0}(G) = \frac{(RERI)P(E = 1)}{(RR_{10} - 1) + (RERI)P(E = 1)}.$$

Often a logistic regression model is used in analyzing data with a binary outcome on the ratio scale. Consider the logistic regression model

$$\text{logit}\{P(Y = 1|G = g, E = e)\} = \gamma_0 + \gamma_1 g + \gamma_2 e + \gamma_3 eg. \quad (2)$$

If the outcome is rare, then odds ratios approximate risk ratios and $RERI$ is given approximately by $RERI \approx e^{\gamma_1 + \gamma_2 + \gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1$ and RR_{10} and RR_{01} can be estimated approximately by $RR_{10} \approx e^{\gamma_1}$ and $RR_{01} \approx e^{\gamma_2}$. We can thus still estimate all of the components of the proportions attributable to interaction using the estimates from the logistic regression in (2) and could compute these proportions by:

$$\begin{aligned} pAI_{G=0}(E) &\approx \frac{(e^{\gamma_1 + \gamma_2 + \gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1)P(G = 1)}{(e^{\gamma_2} - 1) + (e^{\gamma_1 + \gamma_2 + \gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1)P(G = 1)} \\ pAI_{E=0}(G) &\approx \frac{(e^{\gamma_1 + \gamma_2 + \gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1)P(E = 1)}{(e^{\gamma_1} - 1) + (e^{\gamma_1 + \gamma_2 + \gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1)P(E = 1)}. \end{aligned}$$

As discussed in the Appendix, these same expressions can be used even when control is made for covariates in the logistic regression. This approach also works when using logistic

regression in a case-control study. If the outcome is rare or incidence density sampling is used then we can estimate the various components in the decomposition by $RR_{10} \approx e^{\gamma_1}$, $RR_{01} \approx e^{\gamma_2}$, and $RERI \approx e^{\gamma_1+\gamma_2+\gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1$ and, in addition, $P(G = 1)$ and $P(E = 1)$ can be estimated approximately in a case control study using the probability of G and E respectively among the controls. Thus we can proceed with estimating the components of the decomposition, even in a case-control study.

Standard errors for these various expressions, using the delta method, along with SAS code to estimate proportions attributable to interaction and their standard errors, using logistic regression, are given in the eAppendix. A similar approach can also be employed if control is made for some set of covariates C or if one or both of the exposures are continuous rather than binary; see eAppendix for details.

Relaxing the Independence Assumption

All of our discussion up until now has assumed that the two exposures are independent in the population. This assumption may not always be plausible. If G and E represent genetic and environmental exposures then the assumption of independence in the population is often not unreasonable, though there are of course documented cases^{4,5} in which genetic variants do affect environmental exposures and so the assumption has to be assessed on a case-by-case basis. When the exposures are two environmental factors, or two behavioral exposures the two exposures will often, perhaps even most of the time, be correlated with each other. In this section we will consider what can be concluded when the two exposures are not independent, but are instead correlated.

We will assume here that the ordering of the two exposures is known e.g. that G precedes E . In this setting, even if G affects E , the decompositions we have considered in the previous sections will still apply for the second exposure, i.e. for E , provided the effect of E on Y is unconfounded conditional on G (and conditional on, if applicable, measured covariates C). Under this unconfoundedness assumption for E we will still have that the total effect of E decomposes into the sum $(p_{01} - p_{00}) + (p_{11} - p_{10} - p_{01} + p_{00})P(G = 1)$ on the absolute risk scale and can use the sum of these two components as our estimate of the total effect and likewise the regression method in the previous section will still be applicable and $\frac{(p_{11} - p_{10} - p_{01} + p_{00})P(G=1)}{(p_{01} - p_{00}) + (p_{11} - p_{10} - p_{01} + p_{00})P(G=1)}$ would constitute the proportion of the effect attributable to interaction. And similarly on the ratio scale, $\frac{(RERI)P(G=1)}{(RR_{01} - 1) + (RERI)P(G=1)}$ would still constitute the proportion of the effect attributable to interaction. The methods in the previous two sections still apply even if G affects E , or if G and E are otherwise correlated. However, the decomposition of a total effect into a conditional effect and an interaction considered in previous sections do not apply directly for the first exposure G , when G affects E .

Intuitively, this is because the effect of G on Y does not only depend on the presence or absence of E , but it is also the case that whether E is itself present (and thus whether the interaction operates) depends on G . Said another way, if G affects E , E is not simply an effect modifier for G , but it is also potentially a mediator for G . Our decompositions above are no longer applicable. An alternative decomposition does, however, hold. Specifically it can be shown (see Appendix) that when G affects E , we have the following decomposition for the total effect of G : $(p_{g=1} - p_{g=0}) =$

$$(p_{10} - p_{00}) + (p_{11} - p_{10} - p_{01} + p_{00})P(E = 1|G = 1) + (p_{01} - p_{00})\{P(E = 1|G = 1) - P(E = 1|G = 0)\}.$$

The decomposition of the total effect of G , $(p_{g=1} - p_{g=0})$, now consists of three components.

We will consider each component in turn. The first component $(p_{10} - p_{00})$ is simply the effect of G in the absence of E i.e. the portion of the effect of G that would remain if E were fixed to 0. This is analogous to the first component in the two-way decompositions above. The second component, $(p_{11} - p_{10} - p_{01} + p_{00})P(E = 1|G = 1)$, is the effect attributable to interaction, but now the interaction term, $(p_{11} - p_{10} - p_{01} + p_{00})$, is multiplied by $P(E = 1|G = 1)$ when G affects E rather than by $P(E = 1)$, as when G and E were independent; note when G and E are independent, $P(E = 1|G = 1)$ reduces to $P(E = 1)$. The third component, $(p_{01} - p_{00})\{P(E = 1|G = 1) - P(E = 1|G = 0)\}$, was absent from the two-way decomposition; it is essentially the main effect of E in the absence of G , $(p_{01} - p_{00})$, multiplied by the effect of G on E , $\{P(E = 1|G = 1) - P(E = 1|G = 0)\}$; it could be interpreted as a mediated main effect; note again when G and E are independent $P(E = 1|G = 1) - P(E = 1|G = 0) = 0$ and thus this third component vanishes.

Thus when G affects E and we are decomposing the total effect of G two things happen to the decomposition we had under independence. First, because G affects E , we need to take into account the fact that the presence of E (and thus the possibility that the interaction between the two operates) is itself affected by G and thus the interaction term in the second component is multiplied by $P(E = 1|G = 1)$, rather than $P(E = 1)$. Second, when G affects E , a change in G from 0 to 1 will also change E and thus the main effect of E is more likely to operate and we thus introduce a third component, $(p_{01} - p_{00})\{P(E = 1|G = 1) - P(E = 1|G = 0)\}$ to the decomposition.

Under this setting of G affecting E , the proportion of the effect attributable to interaction becomes:

$$pAI_{E=0}(G) = \frac{(p_{11} - p_{10} - p_{01} + p_{00})P(E = 1|G = 1)}{(p_{g=1} - p_{g=0})}.$$

In this context, we might also wonder what the consequences are of ignoring dependence between G and E and proceeding with estimating the proportion attributable to interaction measure when independence of G and E is (incorrectly) assumed i.e. of using the measure

$$pAI_{E=0}(G) = \frac{(p_{11} - p_{10} - p_{01} + p_{00})P(E = 1)}{(p_{g=1} - p_{g=0})}.$$

It is shown in the Appendix that if the latter measure is used for the proportion attributable to interaction, incorrectly assuming independence, then although the latter measure does not actually capture the proportion of the effect attributable to interaction, it does nonetheless constitute a lower bound on the proportion of the effect of G that would be eliminated by fixing E to 0, provided G has a non-negative effect on E , and provided E has a non-negative effect on Y (at least in the absence of G). Thus even if one proceeds with the more naive estimate of the proportion attributable to interaction, ignoring (incorrectly) the dependence between G and E one still, under fairly reasonable assumptions, obtains a lower bound on the proportion of the effect of G eliminated by fixing E to 0.

Further extensions to this approach of relaxing the assumption of independence are discussed in the Appendix and this is generalized to non-binary exposures and outcomes, to the ratio scale, and to settings in which covariates are needed to control for confounding.

When G affects E , two other alternative approaches are worth noting. First instead of decomposing the total effect into a component due to interaction and the various main effects, one might alternatively use methods for mediation. If G affects E and E affects Y , then E will in general be a mediator for the effect of G on Y and one can assess how much of the effect of G on Y is mediated by E . Methods for mediation and easy-to-use software

packages^{6,7} are now available to carry out such mediation analysis and these methods now also allow for interactions between the two exposures G and E .^{7,8} Since these methods are described elsewhere we will not consider them in detail here. It should be noted, however, that these methods address different questions than the ones we have been considering in this paper. However, when G affects the second exposure E , the questions concerning mediation may be the more relevant questions of interest. One can use these methods to assess the proportion of the effect of G on Y mediated through E . This proportion mediated measure is related to but not identical with the proportion eliminated discussed above.^{9,10} The proportion eliminated is not always identical to the proportion mediated because it considers what would happen if we fixed the second exposure (the mediator E) to a particular level (rather than allowing G to affect it). See VanderWeele¹⁰ for further discussion. The decomposition above also gives an interpretation to the portion eliminated measure: it states that the difference between the total effect and the portion of the effect that would remain if E were fixed to zero is equal to the sum of the interaction term and the mediated main effect (i.e. the second and third terms in the decomposition above). Second, yet another approach to assess the importance of interaction with regard to G when G itself affects E is to decompose not a total effect of G on Y , but rather to focus on the joint effects of G and E together and to decompose this joint effect. This is the approach we consider in the following section.

Decomposition of Joint Effects into Main Effects and an Interactive Component

Another, and perhaps more obvious, decomposition would be to decompose the joint effects of the two exposures, G and E , into three components, the effect due to G alone, the effect due to E alone and their interaction. On the risk difference scale this is

$$p_{11} - p_{00} = (p_{10} - p_{00}) + (p_{01} - p_{00}) + (p_{11} - p_{10} - p_{01} + p_{00}).$$

We could then also compute the proportion of the effect due to G alone, $\frac{(p_{10}-p_{00})}{(p_{11}-p_{00})}$, due to E alone, $\frac{(p_{01}-p_{00})}{(p_{11}-p_{00})}$, and due to their interaction, $\frac{(p_{11}-p_{10}-p_{01}+p_{00})}{(p_{11}-p_{00})}$. We can carry out a decomposition like this even if G affects E .

On the risk ratio scale, we can decompose the excess relative risk for both exposures $RR_{11} - 1$ into the excess relative risk for G alone, for E alone, and the excess relative risk due to interaction, $RERI$. Specifically we have

$$RR_{11} - 1 = (RR_{10} - 1) + (RR_{01} - 1) + RERI.$$

We could then likewise compute the proportion of the effect due to G alone, $\frac{RR_{10}-1}{RR_{11}-1}$, due to E alone, $\frac{RR_{01}-1}{RR_{11}-1}$, and due to their interaction $\frac{RERI}{RR_{11}-1}$.

Under the logistic regression model in (2) for an outcome that is rare, the joint effect attributable to G alone, E alone, and to their interaction are given approximately by:

$$\begin{aligned} \frac{RR_{10} - 1}{RR_{11} - 1} &\approx \frac{e^{\gamma_1} - 1}{e^{\gamma_1 + \gamma_2 + \gamma_3} - 1} \\ \frac{RR_{01} - 1}{RR_{11} - 1} &\approx \frac{e^{\gamma_2} - 1}{e^{\gamma_1 + \gamma_2 + \gamma_3} - 1} \\ \frac{RERI}{RR_{11} - 1} &\approx \frac{(e^{\gamma_1 + \gamma_2 + \gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1)}{e^{\gamma_1 + \gamma_2 + \gamma_3} - 1}. \end{aligned}$$

As discussed in the Appendix, these same expressions can be used even when control is made for covariates in the logistic regression. In the eAppendix we give standard errors for these proportion measures and SAS code to estimate the proportions and their standard errors and 95% confidence intervals.

Rothman³ considered a measure of interaction that he called the attributable proportion, defined as $\frac{RERI}{RR_{11}}$; the denominator Rothman used was RR_{11} . The measure was meant to capture the proportion of the *disease* in the doubly exposed group that is due to the interaction. Rothman³ also considered an alternative measure, $\frac{RERI}{RR_{11}-1}$, which captured the proportion of the *effect* of both exposures on the additive scale that is due to interaction. Most of the subsequent literature has focused on the former measure; but the latter measure, i.e. using $RR_{11} - 1$, as the denominator in fact has a number of advantages: both measures are then on the additive excess relative risk scale, when the entirety of the effect is due to interaction the interaction the latter measure is then 100% and not some number less than 100%, and the latter measure is moreover invariant to recoding of the outcome.¹¹ Furthermore, as we have shown here, the latter measure is what is involved in the decomposition above. With Rothman's primary measure, $\frac{RERI}{RR_{11}}$, even if all of the joint effect were due to interaction so that the effect of G alone and E alone were both risk ratios of 1, i.e. $RR_{10} = 1$ and $RR_{01} = 1$, we would nevertheless have that Rothman's primary attributable proportion measure would be $\frac{RERI}{RR_{11}} = \frac{RR_{11} - RR_{10} - RR_{01} + 1}{RR_{11}} = \frac{RR_{11} - 1 - 1 + 1}{RR_{11}} = \frac{RR_{11} - 1}{RR_{11}} < 1$ i.e. even if the entirety of the joint effect of both exposures were due to interaction, the attributable proportion measure is still less than 100%. The measure $\frac{RERI}{RR_{11}-1}$ does not have this issue. It is 100% when the main effects of G alone and E alone were both risk ratios of 1 i.e. when the entirety of the joint effect is due to interaction. The measure $\frac{RERI}{RR_{11}-1}$ captures the proportion of the joint effect attributable to interaction. The attributable proportion of joint effects measure, $\frac{RERI}{RR_{11}-1}$, is also attractive from another standpoint. Skrondal¹² criticized Rothman's original attributable proportion measure because, in the presence of covariates, if the risks follow a linear risk model that is additive in the covariates, $P(Y = 1|G = g, E = e, C = c) = \alpha_0 + \alpha_1 g + \alpha_2 e + \alpha_3 ge + \alpha_4 c$, then, although the additive interaction, $p_{11} - p_{10} - p_{01} + p_{00} = \alpha_3$, does not vary across strata of the covariates, Rothman's primary attributable proportion measure, $\frac{RERI}{RR_{11}} = \frac{\alpha_3}{\alpha_0 + \alpha_1 + \alpha_2 + \alpha_3 + \alpha_4 c}$, does vary across strata of the covariates. One may or may not think that this is an important criticism of the attributable proportion measure; however attributable proportion measure for effect, $\frac{RERI}{RR_{11}-1} = \frac{\alpha_3}{\alpha_1 + \alpha_2 + \alpha_3}$, does not vary with the covariates and thus circumvents this criticism entirely.

Empirical Illustration

We illustrate the various decompositions with an example from genetic epidemiology. We use data from a case-control study of lung cancer at Massachusetts General Hospital (Miller et al.¹³) of 1836 cases and 1452 controls. Eligible cases included any person over the age of 18 years; the controls were recruited from among the friends or spouses of cancer patients or the friends or spouses of other surgery patients in the same hospital. The study included information on smoking and genotype information on locus 15q25.1. For simplicity in this illustration, we will code the exposure as binary so that smoking is ever vs. never and the genetic variant is a comparison of 0 vs. 1/2 T alleles at rs8034191. Covariate data include age (continuous), gender and educational history (college degree or more, yes / no). Analyses were limited to Caucasians. Genetic variants on 15q25.1 have been found to be associated with both smoking and lung cancer^{5,14,15} and thus we are in a setting in which

the first exposure G is correlated with the second exposure E . When we fit the logistic regression model in (2), adjusting also for covariates, we obtain estimates: $\gamma_1 = 0.04$ (95% CI: $-0.33, 0.41$), $\gamma_2 = 1.33$ (95% CI: $1.01, 1.64$), $\gamma_3 = 0.49$ (95% CI: $0.08, 0.89$). The main effect of G is small, the main effect of E is large, and the interaction is of moderate size. If we use the regression coefficients to calculate the proportion attributable to interaction for E we obtain a proportion of 36.6% (95% CI: 11.9%, 61.3%). Even if we eliminated the genetic exposure, 63.4% of the effect would remain (36.6% would be eliminated).

We could proceed with a similar analysis with G but because G affects E here we need to be somewhat more careful in interpretation. Here, however, the correlation between G and E , although present, is quite weak, and so the decomposition assuming independence might not be a bad approximation. If we proceed with the decomposition we obtain that the proportion of the effect of G due to interaction is 98.1% (95% CI: 66.1%, 129.9%). Almost all of the effect of G is due to the presence of E and its interaction with E . As discussed above if we can assume that the variants increase smoking, and that smoking increases lung cancer (both reasonable assumptions here) then 98.1% (95% CI: 66.1%, 129.9%). would be a lower bound on the proportion of the effect of G that would be eliminated if we were to eliminate smoking. And, indeed, there is now strong evidence elsewhere that the genetic variants do not have effect on lung cancer for non-smokers.¹⁶ Almost the entirety of the effect of G appears due to the interaction.

If we proceed with the decomposition of the joint effect, then the proportions attributable to G alone, E alone, and to their interaction are:

$$\begin{aligned}\frac{RR_{10} - 1}{RR_{11} - 1} &\approx 0.8\% \text{ (95\% CI: } -6.2\%, 7.7\%) \\ \frac{RR_{01} - 1}{RR_{11} - 1} &\approx 51.4\% \text{ (95\% CI: } 33.4\%, 69.4\%) \\ \frac{RERI}{RR_{11} - 1} &\approx 47.8\% \text{ (95\% CI: } 33.3\%, 62.3\%).\end{aligned}$$

Almost none of the joint effect (comparing both G and E present to both absent) is due to the effect of G in the absence of E , about 51% is due to E in the absence of G and about 48% is due to the interaction between G and E .

Discussion

In this paper we have considered the decomposition of a total effect into a conditional effect when the other exposure is fixed to 0 and a component due to interaction. This decomposition can be done with both exposures if the two exposures are independent, but can only be done with the second exposure in setting in which the first exposure affects the second. Other decompositions for the first exposure are then possible but the interpretation becomes somewhat more complicated. Even in this case, the joint effects of both exposures can still be decomposed into the component due to the first exposure alone, that due to the second exposure alone, and that due to their interaction. In the Appendix fairly general methods are given using linear regression for carrying out these decompositions with binary, ordinal or continuous exposures. In the eAppendix methods and software are provided for these decompositions using logistic regression and linear regression when the outcome is binary or outcomes and the exposures are binary or continuous.

These various decompositions can shed light on the proportion of various effects that are attributable to interaction. Such attribution may help determine the extent to which an

intervention on a potential effect modifier would successfully alter the effect of the exposure of interest. When used for this purpose it is important that it is the effect modifier itself that affects the outcome and that the effect modifier is not simply serving as a proxy for some other variable that does.^{17,18} In other words, we need to make sure we have controlled for confounding for the effects of the effect modifier itself. These issues of confounding control are discussed in greater detail in the Appendix. We have assumed for simplicity throughout the paper that the effects of both factors are unconfounded, but these assumptions need to be thought about more carefully if these measures are to be used in making policy decisions. However, provided such control for confounding for both factors has been made, the measures considered in this paper can be useful in determining how much of an effect could be eliminated by intervening on an effect modifier.

Appendix

Decomposition of a Total Effect into a Conditional Effect and a Portion due to Interaction

We will let G and E denote two exposures of interest which may be binary, continuous or categorical and let Y be an outcome of interest that may be binary or continuous. Let Y_g denote the counterfactual outcome for an individual if G were set to g , let Y_e denote the counterfactual outcome for an individual if E were set to e , and let Y_{ge} denote the counterfactual outcome for an individual if G were set to g and E were set to e . We will say that the effect of G on Y is unconfounded conditional on C if $Y_g \perp\!\!\!\perp G|C$. We will say that the effect of E on Y is unconfounded conditional on C if $Y_e \perp\!\!\!\perp E|C$. We will say the joint effects of G and E on Y are unconfounded conditional on C if $Y_{ge} \perp\!\!\!\perp (G, E)|C$.

Proposition 1. For any two levels e_1 and e_0 of E and any level g_0 of G we have the decomposition:

$$E[Y_{e_1} - Y_{e_0}|c] = E[Y_{e_1} - Y_{e_0}|g_0, c] + \int \{E[Y_{e_1} - Y_{e_0}|g, c] - E[Y_{e_1} - Y_{e_0}|g_0, c]\} dP(g|c).$$

Proof. We have

$$\begin{aligned} E[Y_{e_1} - Y_{e_0}|c] &= E[Y_{e_1} - Y_{e_0}|g_0, c] + E[Y_{e_1} - Y_{e_0}|c] - E[Y_{e_1} - Y_{e_0}|g_0, c] \\ &= E[Y_{e_1} - Y_{e_0}|g_0, c] + \int \{E[Y_{e_1} - Y_{e_0}|g, c] - E[Y_{e_1} - Y_{e_0}|g_0, c]\} dP(g|c). \end{aligned}$$

In Proposition 1, we can decompose a total effect, $E[Y_{e_1} - Y_{e_0}|c]$, into an effect conditional on $G = g_0$, namely, $E[Y_{e_1} - Y_{e_0}|g_0, c]$, and a component which is a summary measure of effect modification, $\int \{E[Y_{e_1} - Y_{e_0}|g, c] - E[Y_{e_1} - Y_{e_0}|g_0, c]\} dP(g|c)$. The proportion attribut-

able to interaction is then defined by $pAI_{G=g_0}(E) = \frac{\int \{E[Y_{e_1} - Y_{e_0}|g, c] - E[Y_{e_1} - Y_{e_0}|g_0, c]\} dP(g|c)}{E[Y_{e_1} - Y_{e_0}|c]}$.

The decomposition here is given at the counterfactual level and, as noted above, it is a decomposition of a total effect into an effect conditional on G and a measure of effect modification. Note that this decomposition and the proportion due to interaction will vary for different values of $G = g_0$ and thus the reference value g_0 must be specified. This reference value was taken as $G = 0$ in the text; it is the value at which the conditional effect, $E[Y_{e_1} - Y_{e_0}|g_0, c]$, is estimated. The decomposition is given for a particular level of the covariates $C = c$ but we can also marginalize over C to obtain $E[Y_{e_1} - Y_{e_0}] = \int E[Y_{e_1} - Y_{e_0}|g_0, c] dP(c) + \int \{E[Y_{e_1} - Y_{e_0}|g, c] - E[Y_{e_1} - Y_{e_0}|g_0, c]\} dP(g, c)$.

Note then, however, that the first term in the decomposition, $\int E[Y_{e_1} - Y_{e_0}|g_0, c] dP(c)$, is the effect of E on Y conditional on $G = g_0$, and marginalized over the distribution $P(C)$. It will not in general equal $E[Y_{e_1} - Y_{e_0}|g_0]$ since $E[Y_{e_1} - Y_{e_0}|g_0, c]$ is marginalized over $P(C)$ rather than $P(C|g_0)$.

Under assumptions about confounding we can identify each component of the decomposition.

Proposition 2. Suppose that the effect of E on Y is unconfounded conditional on (C, G) then:

$$E[Y_{e_1} - Y_{e_0}|g, c] = E[Y|g, e_1, c] - E[Y|g, e_0, c]$$

and we can thus identify the components in Proposition 1 and the right hand-side of the decomposition in Proposition 1 can be written in terms of observed data as: $E[Y_{e_1} - Y_{e_0}|c]$

$$= E[Y|g_0, e_1, c] - E[Y|g_0, e_0, c] + \int \{E[Y|g, e_1, c] - E[Y|g, e_0, c] - E[Y|g_0, e_1, c] + E[Y|g_0, e_0, c]\} dP(g|c).$$

If, moreover, the joint effects of G and E are unconfounded conditional on C then we can write the decomposition as:

$$E[Y_{e_1} - Y_{e_0}|c] = E[Y_{g_0 e_1}|c] - E[Y_{g_0 e_0}|c] + \int \{E[Y_{g e_1}|c] - E[Y_{g e_0}|c] - E[Y_{g_0 e_1}|c] + E[Y_{g_0 e_0}|c]\} dP(g|c).$$

Proof. If the effect of E on Y is unconfounded conditional on (C, G) , then we have $E[Y_{e_1} - Y_{e_0}|g, c] = E[Y|g, e_1, c] - E[Y|g, e_0, c]$. If the joint effects of G and E are unconfounded conditional on C then we have $E[Y|g, e, c] = E[Y_{ge}|c]$ and thus:

$$E[Y_{e_1} - Y_{e_0} | c] = E[Y_{g_0 e_1} | c] - E[Y_{g_0 e_0} | c] + \int \{E[Y_{g e_1} | c] - E[Y_{g e_0} | c] - E[Y_{g_0 e_1} | c] + E[Y_{g_0 e_0} | c]\} dP(g | c).$$

If the effect of E on Y is unconfounded conditional on C alone as would be the case under Proposition 2 if G and E were independent conditional C then we would also have $[Y_{e_1} - Y_{e_0} | c] = E[Y | e_1, c] - E[Y | e_0, c]$. Otherwise, we will not have $[Y_{e_1} - Y_{e_0} | c] = E[Y | e_1, c] - E[Y | e_0, c]$, but we could still obtain $E[Y_{e_1} - Y_{e_0} | c]$ under Proposition 2 using the sum of the two components, $E[Y | g_0, e_1, c] - E[Y | g_0, e_0, c]$ and $\int \{E[Y | g, e_1, c] - E[Y | g, e_0, c] - E[Y | g_0, e_1, c] + E[Y | g_0, e_0, c]\} dP(g | c)$.

Note that in the second part of Proposition 2, to obtain the decomposition, $E[Y_{e_1} - Y_{e_0} | c] = E[Y_{g_0 e_1} | c] - E[Y_{g_0 e_0} | c] + \int \{E[Y_{g e_1} | c] - E[Y_{g e_0} | c] - E[Y_{g_0 e_1} | c] + E[Y_{g_0 e_0} | c]\} dP(g | c)$, we required that joint effects of both G and E on Y were unconfounded given C . Under this assumption, what we estimate as the portion attributable to interaction is equal to the difference, $E[Y_{e_1} - Y_{e_0} | c] - \{E[Y_{g_0 e_1} | c] - E[Y_{g_0 e_0} | c]\}$ i.e. to the portion of the effect of E on Y that could be eliminated if we fixed G to g_0 . This measure may be of relevance from a policy perspective insofar as we can determine the extent to which intervening to fix G to some level g_0 would eliminate the effect of E on the outcome. We might thus decide whether to intervene on G in order to eliminate the effect of E . Importantly, however, to interpret the measure in this manner it is important that control is made for confounding for both exposures, G and E . Viewed intuitively, this ensures that it is the effect modifier itself that affects the outcome and that the effect modifier is not simply serving as a proxy for some other variable that does.^{17,18} When this is the case the proportion attributable to interaction is equal to the proportion eliminated by fixing G to g_0 .

If no covariates are necessary for confounding control and we let $p_{ge} = P(Y = 1 | G = g, E = e)$, $p_g = P(Y = 1 | G = g)$, and $p_e = P(Y = 1 | E = e)$ then the first decomposition in Proposition 2 written in terms of the observed data simplifies to:

$$(p_{e=1} - p_{e=0}) = (p_{01} - p_{00}) + (p_{11} - p_{10} - p_{01} + p_{00})P(G = 1).$$

and the second decomposition written in terms of counterfactuals simplifies to

$$E[Y_{e=1} - Y_{e=0}] = E[Y_{01} - Y_{00} | c] + E[Y_{11} - Y_{10} - Y_{01} + Y_{00}]P(G = 1).$$

For the linear model

$$E[Y | G = g, E = e, C = c] = \alpha_0 + \alpha_1 g + \alpha_2 e + \alpha_3 eg + \alpha'_4 c,$$

we have

$$\begin{aligned} E[Y | g, e_1, c] - E[Y | g, e_0, c] &= (\alpha_0 + \alpha_1 g + \alpha_2 e_1 + \alpha_3 e_1 g + \alpha'_4 c) - (\alpha_0 + \alpha_1 g + \alpha_2 e_0 + \alpha_3 e_0 g + \alpha'_4 c) \\ &= (\alpha_2 + g\alpha_3)(e_1 - e_0) \end{aligned}$$

and thus the first component in the empirical decomposition in Proposition 2 is equal to:

$$E[Y | g_0, e_1, c] - E[Y | g_0, e_0, c] = (\alpha_2 + g_0\alpha_3)(e_1 - e_0)$$

and the second is equal to:

$$\begin{aligned}
& \int \{E[Y|g, e_1, c] - E[Y|g, e_0, c] - E[Y|g_0, e_1, c] + E[Y|g_0, e_0, c]\} dP(g|c) \\
&= \int (\alpha_2 + g\alpha_3)(e_1 - e_0) - (\alpha_2 + g_0\alpha_3)(e_1 - e_0) dP(g|c) \\
&= \alpha_3 \{E[G|c] - g_0\} (e_1 - e_0).
\end{aligned}$$

The proportion due to interaction is then $\frac{\alpha_3 \{E[G|c] - g_0\}}{(\alpha_2 + \alpha_3 E[G|c])}$. When G and E are binary and $g_0 = 0$ and there are no covariates, the two components reduce to α_2 and $\alpha_3 P(G = 1)$ and the proportion due to interaction is $\frac{\alpha_3 P(G=1)}{\alpha_2 + \alpha_3 P(G=1)}$, as in the text. Note, however, that when the exposures are not binary the measures themselves (and thus the proportion attributable to interaction) may vary depending on the values, e_1 and e_0 , of E that are being compared, also and also again on the reference value, g_0 of G .

On the risk ratio scale, we let $RR_{g=1} = \frac{p_{g=1}}{p_{g=0}} = \frac{P(Y=1|G=1)}{P(Y=1|G=0)}$ and $RR_{e=1} = \frac{p_{e=1}}{p_{e=0}} = \frac{P(Y=1|E=1)}{P(Y=1|E=0)}$ and $RR_{ge} = \frac{p_{ge}}{p_{00}} = \frac{P(Y=1|G=g, E=e)}{P(Y=1|G=0, E=0)}$. The decomposition $(p_{e=1} - p_{e=0}) = (p_{01} - p_{00}) + (p_{11} - p_{10} - p_{01} + p_{00})P(G = 1)$ when divided by $p_{e=0}$ is

$$(RR_{e=1} - 1) = \kappa(RR_{01} - 1) + \kappa(RR_{11} - RR_{10} - RR_{01} + 1)P(G = 1).$$

where κ is a scaling factor given by $\kappa = \frac{p_{00}}{p_{e=0}}$. The proportion of the effect of E attributable to interaction is given by:

$$pAI_{G=0}(E) = \frac{(RR_{11} - RR_{10} - RR_{01} + 1)P(G = 1)}{(RR_{01} - 1) + (RR_{11} - RR_{10} - RR_{01} + 1)P(G = 1)}.$$

As noted in the text, if we use the logistic regression model

$$\logit\{P(Y = 1|G = g, E = e, C = c)\} = \gamma_0 + \gamma_1 g + \gamma_2 e + \gamma_3 eg + \gamma_4' c.$$

then proportion attributed to interaction if the exposures are binary can be approximated by $pAI_{G=0}(E) \approx \frac{(e^{\gamma_1 + \gamma_2 + \gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1)P(G=1)}{(e^{\gamma_2} - 1) + (e^{\gamma_1 + \gamma_2 + \gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1)P(G=1)}$. In the eAppendix we discuss estimating standard errors for this proportion attributed to interaction.

Analogous Results for G

Note that, by symmetry, from Proposition 1, we have the decomposition

$$E[Y_{g_1} - Y_{g_0}|c] = E[Y_{g_1} - Y_{g_0}|e_0, c] + \int \{E[Y_{g_1} - Y_{g_0}|e, c] - E[Y_{g_1} - Y_{g_0}|e_0, c]\} dP(e|c).$$

This decomposition applies even if G affects E . If G and E were independent so that G did not affect E , then we would have an analogue of Proposition 2 which would be that if the effect of G on Y is unconfounded conditional on (C, E) then we have $E[Y_{g_1} - Y_{g_0}|e, c] = E[Y|g_1, e, c] - E[Y|g_0, e, c]$, and under independence also, $E[Y_{g_1} - Y_{g_0}|c] = E[Y|g_1, c] - E[Y|g_0, c]$, and we can thus write the decomposition of the total effect of G in terms of

observed data as: $E[Y|g_1, c] - E[Y|g_0, c]$

$$= E[Y|g_1, e_0, c] - E[Y|g_0, e_0, c] + \int \{E[Y|g_1, e, c] - E[Y|g_0, e, c] - E[Y|g_1, e_0, c] + E[Y|g_0, e_0, c]\} dP(e|c).$$

If, moreover, the joint effects of G and E are unconfounded conditional on C then we can write the decompositions as:

$$E[Y_{g_1} - Y_{g_0}|c] = E[Y_{g_1 e_0} - Y_{g_0 e_0}|c] + \int \{E[Y_{g_1 e} - Y_{g_0 e}|c] - E[Y_{g_1 e_0} - Y_{g_0 e_0}|c]\} dP(e|c).$$

Settings in which G Affects E

If G affects E , then the conditions in Proposition 2 still apply. We can still thus empirically decompose the total effect of E on Y into a conditional effect and the portion due to interaction. If G affects E we no longer have the simple relation $[Y_{e_1} - Y_{e_0}|c] = E[Y|e_1, c] - E[Y|e_0, c]$ because control for G will in general be needed to control for confounding for E . But we can still obtain $E[Y_{e_1} - Y_{e_0}|c]$, even if G affects E under Proposition 2, using the sum of the two components, $E[Y|g_0, e_1, c] - E[Y|g_0, e_0, c]$ and $\int \{E[Y|g, e_1, c] - E[Y|g, e_0, c] - E[Y|g_0, e_1, c] + E[Y|g_0, e_0, c]\} dP(g)$.

However, if G affects E then the analogue of Proposition 2 for G will not apply. We still have the analogous decomposition to that in Proposition 1:

$$E[Y_{g_1} - Y_{g_0}|c] = E[Y_{g_1} - Y_{g_0}|e_0, c] + \int \{E[Y_{g_1} - Y_{g_0}|e, c] - E[Y_{g_1} - Y_{g_0}|e_0, c]\} dP(e|c).$$

However, the counterfactuals of the form $E[Y_{g_1} - Y_{g_0}|e_0, c]$ will not be identified and so we cannot empirically estimate the various parts of the decomposition. This is because when G affects E , the analogue Proposition 2 for G would require that the effect of G on Y is unconfounded on (C, E) and this fails because G itself affects E .

However, when G affects E we still have the decomposition in the Proposition below.

Proposition 3. If the effect of G on Y is unconfounded conditional on C , and the effects of G and E are unconfounded conditional on C then we have

$$\begin{aligned} E[Y_{g_1} - Y_{g_0}|c] &= E[Y_{g_1 e_0} - Y_{g_0 e_0}|c] + \int \{E[Y_{g_1 e} - Y_{g_0 e}|c] - E[Y_{g_1 e_0} - Y_{g_0 e_0}|c]\} dP(e|g_1, c) \\ &\quad + \int \{E[Y_{g_0 e} - Y_{g_0 e_0}|c]\} \{dP(e|g_1, c) - dP(e|g_0, c)\}. \end{aligned}$$

Moreover, each component of the decomposition above identified and the corresponding decomposition expressed in terms of the observed data is $E[Y_{g_1} - Y_{g_0}|c]$

$$\begin{aligned} &= \{E[Y|g_1, e_0, c] - E[Y|g_0, e_0, c]\} \\ &\quad + \int \{E[Y|g_1, e, c] - E[Y|g_0, e, c]\} - \{E[Y|g_1, e_0, c] - E[Y|g_0, e_0, c]\} dP(e|g_1, c) \\ &\quad + \int \{E[Y|g_0, e, c] - E[Y|g_0, e_0, c]\} \{dP(e|g_1, c) - dP(e|g_0, c)\}. \end{aligned}$$

Proof. We have that $E[Y_{g_1} - Y_{g_0}|c]$

$$\begin{aligned}
&= E[Y|g_1, c] - E[Y|g_0, c] \\
&= E[Y|g_1, e_0, c] - E[Y|g_0, e_0, c] + \{E[Y|g_1, c] - E[Y|g_1, e_0, c]\} - \{E[Y|g_0, c] - E[Y|g_0, e_0, c]\} \\
&= E[Y|g_1, e_0, c] - E[Y|g_0, e_0, c] + \int \{E[Y|g_1, e, c] - E[Y|g_1, e_0, c]\} dP(e|g_1, c) \\
&\quad - \int \{E[Y|g_0, e, c] - E[Y|g_0, e_0, c]\} dP(e|g_0, c) \\
&= \{E[Y|g_1, e_0, c] - E[Y|g_0, e_0, c]\} \\
&\quad + \int \{E[Y|g_1, e, c] - E[Y|g_0, e, c]\} - \{E[Y|g_1, e_0, c] - E[Y|g_0, e_0, c]\} dP(e|g_1, c) \\
&\quad + \int \{E[Y|g_0, e, c] - E[Y|g_0, e_0, c]\} \{dP(e|g_1, c) - dP(e|g_0, c)\} \\
&= E[Y_{g_1 e_0} - Y_{g_0 e_0}|c] + \int \{E[Y_{g_1 e} - Y_{g_0 e}|c] - E[Y_{g_1 e_0} - Y_{g_0 e_0}|c]\} dP(e|g_1, c) \\
&\quad + \int \{E[Y_{g_0 e} - Y_{g_0 e_0}|c]\} \{dP(e|g_1, c) - dP(e|g_0, c)\}.
\end{aligned}$$

In the decomposition above, the first term, $E[Y_{g_1 e_0} - Y_{g_0 e_0}|c] = \{E[Y|g_1, e_0, c] - E[Y|g_0, e_0, c]\}$ is the controlled direct effect^{9,10} of G , comparing levels, g_1 and g_0 , when E is fixed to e_0 . The second term, $\int \{E[Y_{g_1 e} - Y_{g_0 e}|c] - E[Y_{g_1 e_0} - Y_{g_0 e_0}|c]\} dP(e|g_1, c)$, is the portion attributable to interaction; it is an interaction, $E[Y_{g_1 e} - Y_{g_0 e}|c] - E[Y_{g_1 e_0} - Y_{g_0 e_0}|c]$, standardized by the distribution, $P(e|g_1, c)$. The third and final term, $\int \{E[Y_{g_0 e} - Y_{g_0 e_0}|c]\} \{dP(e|g_1, c) - dP(e|g_0, c)\}$, is the main effect of E when $G = g_0$, standardized by $P(e|g_1, c)$ versus $P(e|g_0, c)$, which, provided the effect of G on E is unconfounded conditional on C , is essentially the effect of G on E and thus the third term is in some sense a mediated main effect.

When G , E and Y are binary and $g_0 = 0$ is selected as the reference level, and no covariates are required for confounding, the decomposition reduces to: $E[Y_1 - Y_0]$

$$\begin{aligned}
&= E[Y_{10} - Y_{00}] + E[Y_{11} - Y_{01} - Y_{10} - Y_{00}]P(E = 1|G = 1) \\
&\quad + E[Y_{01} - Y_{00}]\{P(E = 1|G = 1) - P(E = 1|G = 0)\}.
\end{aligned}$$

Or, expressed in terms of the observed data, as $(p_{g=1} - p_{g=0})$

$$\begin{aligned}
&= (p_{10} - p_{00}) + (p_{11} - p_{10} - p_{01} + p_{00})P(E = 1|G = 1) \\
&\quad + (p_{01} - p_{00})\{P(E = 1|G = 1) - P(E = 1|G = 0)\}
\end{aligned}$$

as in the text. The proportion attributable to interaction is then:

$$pAI_{E=0}(G) = \frac{(p_{11} - p_{10} - p_{01} + p_{00})P(E = 1|G = 1)}{(p_{g=1} - p_{g=0})}.$$

Note that when G has a non-negative effect on E , and E has a non-negative effect on Y (in the absence of G) so that $P(E = 1|G = 1) - P(E = 1|G = 0) \geq 0$ and thus $P(E = 1) = P(E = 1|G = 1)P(G = 1) + P(E = 1|G = 0)P(G = 0) \leq P(E = 1|G = 1)$ and

$(p_{01} - p_{00})\{P(E = 1|G = 1) - P(E = 1|G = 0)\} \geq 0$ we then have that $(p_{11} - p_{10} - p_{01} + p_{00})P(E = 1) \leq (p_{11} - p_{10} - p_{01} + p_{00})P(E = 1|G = 1) = (p_{g=1} - p_{g=0}) - (p_{10} - p_{00}) - (p_{01} - p_{00})\{P(E = 1|G = 1) - P(E = 1|G = 0)\} \leq (p_{g=1} - p_{g=0}) - (p_{10} - p_{00})$ and from this it follows that if the dependence between G and E is incorrectly ignored and

$$\frac{(p_{11} - p_{10} - p_{01} + p_{00})P(E = 1)}{(p_{g=1} - p_{g=0})}.$$

is used for the proportion attributable to interaction, then although the latter measure does not actually capture the proportion of the effect attribution to interaction, it does nonetheless constitute a lower bound on the proportion of the effect of G that would be eliminated by fixing E to 0, as indicated in the text. Thus even if one proceeds with the more naive estimate of the proportion attributable to interaction, ignoring (incorrectly) the dependence between G and E one still, under fairly reasonable assumptions, obtains a lower bound on the proportion of the effect of G eliminated by fixing E to 0.

The decomposition, $(p_{g=1} - p_{g=0}) = (p_{10} - p_{00}) + (p_{11} - p_{10} - p_{01} + p_{00})P(E = 1|G = 1) + (p_{01} - p_{00})\{P(E = 1|G = 1) - P(E = 1|G = 0)\}$ when divided by $p_{g=0}$ is

$$\begin{aligned} (RR_{g=1} - 1) &= \kappa(RR_{10} - 1) + \kappa(RR_{11} - RR_{10} - RR_{01} + 1)P(E = 1|G = 1) \\ &\quad + \kappa(RR_{01} - 1)\{P(E = 1|G = 1) - P(E = 1|G = 0)\}. \end{aligned}$$

where κ is a scaling factor given by $\kappa = \frac{p_{00}}{p_{e=0}}$. The proportion of the effect of G attributable to interaction is:

$$pAI_{E=0}(G) = \frac{(RR_{11} - RR_{10} - RR_{01} + 1)P(E=1|G=1)}{(RR_{10} - 1) + (RR_{11} - RR_{10} - RR_{01} + 1)P(E=1|G=1) + (RR_{01} - 1)\{P(E=1|G=1) - P(E=1|G=0)\}}.$$

Decomposition of Joint Effects

At the counterfactual level, we can decompose the joint effects of the two exposures, G and E , into the effect due to G alone, the effect due to E alone and their interaction. We have:

$$E[Y_{g_1 e_1} - Y_{g_0 e_0} | c] = E[Y_{g_1 e_0} - Y_{g_0 e_0} | c] + E[Y_{g_0 e_1} - Y_{g_0 e_0} | c] + E[Y_{g_1 e_1} - Y_{g_1 e_0} - Y_{g_0 e_1} + Y_{g_0 e_0} | c]$$

If the joint effects of G and E are unconfounded conditional on C each of these components is identified from the observed data and the decomposition can be rewritten as:

$$\begin{aligned} E[Y|g_1, e_1, c] - E[Y|g_0, e_0, c] &= \{E[Y|g_1, e_0, c] - E[Y|g_0, e_0, c]\} + \{E[Y|g_0, e_1, c] - E[Y|g_0, e_0, c]\} \\ &\quad + \{E[Y|g_1, e_1, c] - E[Y|g_1, e_0, c] - E[Y|g_0, e_1, c] + E[Y|g_0, e_0, c]\}. \end{aligned}$$

We can then also compute the proportion of the joint effect due G alone as $\frac{E[Y|g_1, e_0, c] - E[Y|g_0, e_0, c]}{E[Y|g_1, e_1, c] - E[Y|g_0, e_0, c]}$,

due to E alone as $\frac{E[Y|g_0, e_1, c] - E[Y|g_0, e_0, c]}{E[Y|g_1, e_1, c] - E[Y|g_0, e_0, c]}$, and due to their interaction as

$\frac{E[Y|g_1, e_1, c] - E[Y|g_1, e_0, c] - E[Y|g_0, e_1, c] + E[Y|g_0, e_0, c]}{E[Y|g_1, e_1, c] - E[Y|g_0, e_0, c]}$. Dividing the first decomposition above by

$E[Y_{g_0 e_0} | c]$, or the second by $E[Y|g_0, e_0, c]$, or both the numerator and the denominator of the proportions by $E[Y|g_0, e_0, c]$ yields decompositions and proportions on the ratio scale. All of these decompositions are applicable even if G affects E .

On a difference scale, under the linear model

$$E[Y|G = g, E = e, C = c] = \alpha_0 + \alpha_1 g + \alpha_2 e + \alpha_3 eg + \alpha'_4 c,$$

we have that the three components are given by:

$$\begin{aligned}\{E[Y|g_1, e_0, c] - E[Y|g_0, e_0, c]\} &= (\alpha_1 + \alpha_3 e_0)(g_1 - g_0) \\ \{E[Y|g_0, e_1, c] - E[Y|g_0, e_0, c]\} &= (\alpha_2 + \alpha_3 g_0)(e_1 - e_0) \\ \{E[Y|g_1, e_1, c] - E[Y|g_1, e_0, c] - E[Y|g_0, e_1, c] + E[Y|g_0, e_0, c]\} &= \alpha_3(g_1 e_1 - g_1 e_0 - g_0 e_1 + g_0 e_0).\end{aligned}$$

When G and E are binary, these three components reduce to α_1 , α_2 , and α_3 , respectively. Note, however, that when the exposures are not binary the measures themselves (and thus the proportion attributable to each component) may vary depending on the values, e_1 and e_0 , of E and the values, g_1 and g_0 , of G that are being compared.

On a ratio scale, under the logistic regression model with a rare outcome,

$$\text{logit}\{P(Y = 1|G = g, E = e, C = c)\} = \gamma_0 + \gamma_1 g + \gamma_2 e + \gamma_3 eg + \gamma_4' c$$

if G and E then the proportions discussed in the text of the joint effect attributable to G alone, E alone, and to their interaction are given approximately by:

$$\begin{aligned}\frac{RR_{10} - 1}{RR_{11} - 1} &\approx \frac{e^{\gamma_1} - 1}{e^{\gamma_1 + \gamma_2 + \gamma_3} - 1} \\ \frac{RR_{01} - 1}{RR_{11} - 1} &\approx \frac{e^{\gamma_2} - 1}{e^{\gamma_1 + \gamma_2 + \gamma_3} - 1} \\ \frac{RERI}{RR_{11} - 1} &\approx \frac{(e^{\gamma_1 + \gamma_2 + \gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1)}{e^{\gamma_1 + \gamma_2 + \gamma_3} - 1},\end{aligned}$$

respectively. See the eAppendix for standard errors.

eAppendix

1. Binary Exposures and Binary Outcomes

1.1. Standard Error for the Proportion of a Total Effect Attributable to Interaction

As noted in the text, for a binary outcome and two binary exposures G and E , the proportion of the excess relative risk for E that is attributable to interaction is given by:

$$pAI_{G=0}(E) = \frac{(RERI)P(G = 1)}{(RR_{01} - 1) + (RERI)P(G = 1)}.$$

where $RERI = RR_{11} - RR_{10} - RR_{01} + 1$. Under the logistic regression model with a rare outcome

$$\text{logit}\{P(Y = 1|G = g, E = e, C = c)\} = \gamma_0 + \gamma_1 g + \gamma_2 e + \gamma_3 eg + \gamma_4' c, \quad (A1)$$

the proportion attributable to interaction is given by:

$$pAI_{G=0}(E) \approx \frac{(e^{\gamma_1 + \gamma_2 + \gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1)P(G = 1)}{(e^{\gamma_2} - 1) + (e^{\gamma_1 + \gamma_2 + \gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1)P(G = 1)}.$$

For the standard error for the proportion due to interaction we will assume that the proportion $P(G = 1)$ is known. Alternatively, the standard errors derived can be interpreted as standard errors for the estimate of the proportion attributable to interaction in a population which had the same underlying risk ratios as the sample in question, but had a prevalence of G equal to the prevalence of G in the sample.

Let

$$V = \begin{pmatrix} v_{00} & v_{01} & v_{02} & v_{03} \\ v_{10} & v_{11} & v_{12} & v_{13} \\ v_{20} & v_{21} & v_{22} & v_{23} \\ v_{30} & v_{31} & v_{32} & v_{33} \end{pmatrix}$$

be the covariance matrix for the estimators $(\hat{\gamma}_0, \hat{\gamma}_1, \hat{\gamma}_2, \hat{\gamma}_3)'$ of $(\gamma_0, \gamma_1, \gamma_2, \gamma_3)'$. By the delta method the variance of our estimator $\hat{Q}$ of $Q = \frac{(e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_1-e^{\gamma_2}+1})P(G=1)}{(e^{\gamma_2-1})+(e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_1-e^{\gamma_2}+1})P(G=1)}$ replacing $(\gamma_0, \gamma_1, \gamma_2, \gamma_3)$ in this expression with $(\hat{\gamma}_0, \hat{\gamma}_1, \hat{\gamma}_2, \hat{\gamma}_3)'$ is given by:

$$Var(Q) = \frac{\partial Q}{\partial(\gamma_0, \gamma_1, \gamma_2, \gamma_3)'}' V \frac{\partial Q}{\partial(\gamma_0, \gamma_1, \gamma_2, \gamma_3)'}$$

We have that $\frac{\partial Q}{\partial(\gamma_0, \gamma_1, \gamma_2, \gamma_3)'} =$

$$\begin{pmatrix} 0 \\ \frac{[(e^{\gamma_2-1})+(e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_1-e^{\gamma_2}+1})P(G=1)][(e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_1})P(G=1)]-[(e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_1-e^{\gamma_2}+1})P(G=1)][(e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_1})P(G=1)]}{[(e^{\gamma_2-1})+(e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_1-e^{\gamma_2}+1})P(G=1)][(e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_2})P(G=1)]-[(e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_1-e^{\gamma_2}+1})P(G=1)][e^{\gamma_2}+(e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_2})P(G=1)]} \\ \frac{[(e^{\gamma_2-1})+(e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_1-e^{\gamma_2}+1})P(G=1)][(e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_1-e^{\gamma_2}+1})P(G=1)]^2}{[(e^{\gamma_2-1})+(e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_1-e^{\gamma_2}+1})P(G=1)][e^{\gamma_2}+(e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_2})P(G=1)]^2} \\ \frac{[(e^{\gamma_2-1})+(e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_1-e^{\gamma_2}+1})P(G=1)][e^{\gamma_1+\gamma_2+\gamma_3}]-[(e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_1-e^{\gamma_2}+1})P(G=1)][e^{\gamma_1+\gamma_2+\gamma_3}]}{[(e^{\gamma_2-1})+(e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_1-e^{\gamma_2}+1})P(G=1)]^2} \end{pmatrix}$$

$$= \begin{pmatrix} 0 \\ \frac{[(e^{\gamma_2-1})[(e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_1})P(G=1)]]}{[(e^{\gamma_2-1})+(e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_1-e^{\gamma_2}+1})P(G=1)]^2} \\ \frac{-(e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_2})P(G=1)}{[(e^{\gamma_2-1})+(e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_1-e^{\gamma_2}+1})P(G=1)]^2} \\ \frac{(e^{\gamma_2-1})[e^{\gamma_1+\gamma_2+\gamma_3}]}{[(e^{\gamma_2-1})+(e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_1-e^{\gamma_2}+1})P(G=1)]^2} \end{pmatrix}$$

Let K_1 , K_2 and K_3 denote the first, second, and third non-zero expressions in this vector.

We then have

$$\begin{aligned} Var(\hat{Q}) &= \frac{\partial Q}{\partial(\gamma_0, \gamma_1, \gamma_2, \gamma_3)'}' V \frac{\partial Q}{\partial(\gamma_0, \gamma_1, \gamma_2, \gamma_3)'} \\ &= \begin{pmatrix} 0 \\ K_1 \\ K_2 \\ K_3 \end{pmatrix}' \begin{pmatrix} v_{00} & v_{01} & v_{02} & v_{03} \\ v_{10} & v_{11} & v_{12} & v_{13} \\ v_{20} & v_{21} & v_{22} & v_{23} \\ v_{30} & v_{31} & v_{32} & v_{33} \end{pmatrix} \begin{pmatrix} 0 \\ K_1 \\ K_2 \\ K_3 \end{pmatrix} \\ &= \begin{pmatrix} 0 \\ K_1 \\ K_2 \\ K_3 \end{pmatrix}' \begin{pmatrix} v_{01}K_1 + v_{02}K_2 + v_{03}K_3 \\ v_{11}K_1 + v_{12}K_2 + v_{13}K_3 \\ v_{21}K_1 + v_{22}K_2 + v_{23}K_3 \\ v_{31}K_1 + v_{32}K_2 + v_{33}K_3 \end{pmatrix} \\ &= v_{11}K_1^2 + v_{22}K_2^2 + v_{33}K_3^2 + v_{12}K_1K_2 + v_{13}K_1K_3 + v_{23}K_2K_3. \end{aligned}$$

1.2 Standard Error for the Proportion of a Joint Effect Attributable to Either Exposure Alone and to Interaction

For the three-way decomposition of the joint excess relative risk of both exposures, $RR_{11} - 1$, we have a decomposition into an excess risk relative risk for G alone, an excess relative risk for E alone, and the excess relative risk due to interaction i.e. we have the decomposition: $RR_{11} - 1 = (RR_{10} - 1) + (RR_{01} - 1) + RERI$. And we can compute the proportion of the joint effect due to G alone $\frac{RR_{10}-1}{RR_{11}-1}$, and due to E alone $\frac{RR_{01}-1}{RR_{11}-1}$, and due to their interaction $\frac{RERI}{RR_{11}-1}$. Under the logistic regression model with a rare outcome

$$\text{logit}\{P(Y = 1|G = g, E = e, C = c)\} = \gamma_0 + \gamma_1 g + \gamma_2 e + \gamma_3 eg + \gamma_4 c,$$

the proportion can be estimated approximately by:

$$\begin{aligned} \frac{RR_{10} - 1}{RR_{11} - 1} &\approx \frac{e^{\gamma_1} - 1}{e^{\gamma_1 + \gamma_2 + \gamma_3} - 1} \\ \frac{RR_{01} - 1}{RR_{11} - 1} &\approx \frac{e^{\gamma_2} - 1}{e^{\gamma_1 + \gamma_2 + \gamma_3} - 1} \\ \frac{RERI}{RR_{11} - 1} &\approx \frac{(e^{\gamma_1 + \gamma_2 + \gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1)}{e^{\gamma_1 + \gamma_2 + \gamma_3} - 1}. \end{aligned}$$

We will now compute the standard errors for these expressions.

For the proportion of the joint effect due to a single exposure alone, we have, by the delta method, that the variance of our estimator $\hat{Q}$ of $Q = \frac{e^{\gamma_1}-1}{e^{\gamma_1+\gamma_2+\gamma_3}-1}$ replacing $(\gamma_0, \gamma_1, \gamma_2, \gamma_3)$ in this expression with $(\hat{\gamma}_0, \hat{\gamma}_1, \hat{\gamma}_2, \hat{\gamma}_3)'$ is given by:

$$\text{Var}(Q) = \frac{\partial Q}{\partial(\gamma_0, \gamma_1, \gamma_2, \gamma_3)'}' V \frac{\partial Q}{\partial(\gamma_0, \gamma_1, \gamma_2, \gamma_3)'}$$

We have that $\frac{\partial Q}{\partial(\gamma_0, \gamma_1, \gamma_2, \gamma_3)'} =$

$$\begin{pmatrix} 0 \\ \frac{[e^{\gamma_1 + \gamma_2 + \gamma_3} - 1][e^{\gamma_1} - 1][e^{\gamma_1 + \gamma_2 + \gamma_3}]}{[e^{\gamma_1 + \gamma_2 + \gamma_3} - 1]^2} \\ \frac{[e^{\gamma_1 + \gamma_2 + \gamma_3} - 1][0] - [e^{\gamma_1} - 1][e^{\gamma_1 + \gamma_2 + \gamma_3}]}{[e^{\gamma_1 + \gamma_2 + \gamma_3} - 1]^2} \\ \frac{[e^{\gamma_1 + \gamma_2 + \gamma_3} - 1][0] - [e^{\gamma_1} - 1][e^{\gamma_1 + \gamma_2 + \gamma_3}]}{[e^{\gamma_1 + \gamma_2 + \gamma_3} - 1]^2} \end{pmatrix}.$$

$$\begin{pmatrix} 0 \\ \frac{[e^{\gamma_1 + \gamma_2 + \gamma_3}] - e^{\gamma_1}}{[e^{\gamma_1 + \gamma_2 + \gamma_3} - 1]^2} \\ \frac{-[e^{\gamma_1} - 1][e^{\gamma_1 + \gamma_2 + \gamma_3}]}{[e^{\gamma_1 + \gamma_2 + \gamma_3} - 1]^2} \\ \frac{-[e^{\gamma_1} - 1][e^{\gamma_1 + \gamma_2 + \gamma_3}]}{[e^{\gamma_1 + \gamma_2 + \gamma_3} - 1]^2} \end{pmatrix}.$$

Let K_1 , K_2 and K_3 denote the first, second, and third non-zero expressions in this vector. We then once again have $\text{Var}(\hat{Q}) = v_{11}K_1^2 + v_{22}K_2^2 + v_{33}K_3^2 + v_{12}K_1K_2 + v_{13}K_1K_3 + v_{23}K_2K_3$.

For the standard error for the proportion of a joint effect attributable to interaction we have, by the delta method, that the variance of the estimator $\hat{Q}$ of $Q = \frac{(e^{\gamma_1 + \gamma_2 + \gamma_3} - e^{\gamma_1} - e^{\gamma_2} + 1)}{e^{\gamma_1 + \gamma_2 + \gamma_3} - 1}$ replacing $(\gamma_0, \gamma_1, \gamma_2, \gamma_3)$ in this expression with $(\hat{\gamma}_0, \hat{\gamma}_1, \hat{\gamma}_2, \hat{\gamma}_3)'$ is given by:

$$\text{Var}(Q) = \frac{\partial Q}{\partial(\gamma_0, \gamma_1, \gamma_2, \gamma_3)'}' V \frac{\partial Q}{\partial(\gamma_0, \gamma_1, \gamma_2, \gamma_3)'}$$

We have that $\frac{\partial Q}{\partial(\gamma_0, \gamma_1, \gamma_2, \gamma_3)'} =$

$$\begin{pmatrix} 0 \\ \frac{[e^{\gamma_1+\gamma_2+\gamma_3}-1][e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_1}]-[(e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_1}-e^{\gamma_2}+1)][e^{\gamma_1+\gamma_2+\gamma_3}]}{[e^{\gamma_1+\gamma_2+\gamma_3}-1]^2} \\ \frac{[e^{\gamma_1+\gamma_2+\gamma_3}-1][e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_2}]-[(e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_1}-e^{\gamma_2}+1)][e^{\gamma_1+\gamma_2+\gamma_3}]}{[e^{\gamma_1+\gamma_2+\gamma_3}-1]^2} \\ \frac{[e^{\gamma_1+\gamma_2+\gamma_3}-1][e^{\gamma_1+\gamma_2+\gamma_3}]-[(e^{\gamma_1+\gamma_2+\gamma_3}-e^{\gamma_1}-e^{\gamma_2}+1)][e^{\gamma_1+\gamma_2+\gamma_3}]}{[e^{\gamma_1+\gamma_2+\gamma_3}-1]^2} \end{pmatrix} \\ = \begin{pmatrix} 0 \\ \frac{e^{\gamma_1}+(e^{\gamma_2}-2)[e^{\gamma_1+\gamma_2+\gamma_3}]}{[e^{\gamma_1+\gamma_2+\gamma_3}-1]^2} \\ \frac{e^{\gamma_2}+(e^{\gamma_1}-2)[e^{\gamma_1+\gamma_2+\gamma_3}]}{[e^{\gamma_1+\gamma_2+\gamma_3}-1]^2} \\ \frac{(e^{\gamma_1}+e^{\gamma_2}-2)[e^{\gamma_1+\gamma_2+\gamma_3}]}{[e^{\gamma_1+\gamma_2+\gamma_3}-1]^2} \end{pmatrix}.$$

Let K_1 , K_2 and K_3 denote the first, second, and third non-zero expressions in this vector. We then have $Var(\hat{Q}) = v_{11}K_1^2 + v_{22}K_2^2 + v_{33}K_3^2 + v_{12}K_1K_2 + v_{13}K_1K_3 + v_{23}K_2K_3$.

1.3. SAS Code to Implement Proportion of a Total Effect Attributable to Interaction

Suppose we have a dataset named 'mydata' with outcome variable 'y', exposure variables 'e' and 'g' and three covariates 'c1', 'c2' and 'c3'. To use the code below, the user must input in the third and fourth line of the data step the prevalence of the exposure G ('pg=') and the prevalence of the exposure E ('pg='). In a case-control study, these prevalences should be computed only among the controls. The output will include the proportion of the total effect of G that is attributable to interaction, along with a 95% confidence interval; the remaining proportion is that attributable to G when E is set to 0. The code will also report the proportion of the total effect of E that is attributed to interaction, along with a 95% confidence interval; once again, the remaining proportion is that attributable to E when G is set to 0.

These measures assume that G and E are independent, and that control has been made for confounding. In this case, the proportion attributable to interaction for G can also be interpreted as the proportion of the total effect of G that would be eliminated if E were set to 0. Likewise, the proportion attributable to interaction for E can also be interpreted as the proportion of the total effect of E that would be eliminated if G were set to 0. When G and E are not independent (e.g. G affects E), the measure for the second exposure still carries this interpretation provided control has been made for confounding. However, for the first exposure G the proportion attributable to interaction given in the output corresponds to the proportion of an integrated joint effect due to interaction, as discussed in the Appendix to the paper.

1.4. SAS Code to Implement Proportion of a Joint Effect Attributable to Either Exposure Alone and to Interaction

As discussed in the text it is possible to decompose the joint excess relative risk for both exposures together into three components: (i) a component due to the first exposure G alone, (ii) a component due to E alone, and (iii) a component due to the interaction between the effect of G and E . The output gives the proportions due to G alone, the proportion due to E alone, and the proportion due to the interaction; 95% confidence intervals are also given for these three proportions. The three proportions will sum to 100%. The decomposition applies even if one of the exposures affects the other.

2. Binary Outcome and Continuous Exposures

2.1. Proportion of a Total Effect Attributable to Interaction

As discussed in the Appendix to the text, for continuous exposures, when the effect of E on Y is unconfounded conditional on (C, G) then the total effect of E on Y , $E[Y_{e_1}|c] - E[Y_{e_0}|c]$, could be decomposed into two components as: $E[Y_{e_1}|c] - E[Y_{e_0}|c]$

$$= E[Y|g_0, e_1, c] - E[Y|g_0, e_0, c] + \int \{E[Y|g, e_1, c] - E[Y|g, e_0, c] - E[Y|g_0, e_1, c] + E[Y|g_0, e_0, c]\} dP(g|c)$$

which on the ratio scale can be rewritten as $\frac{E[Y_{e_1}|c]}{E[Y_{e_0}|c]} - 1$

$$= \kappa \left\{ \frac{E[Y|g_0, e_1, c]}{E[Y|g_0, e_0, c]} - 1 \right\} + \kappa \int \left\{ \frac{E[Y|g, e_1, c]}{E[Y|g_0, e_0, c]} - \frac{E[Y|g, e_0, c]}{E[Y|g_0, e_0, c]} - \frac{E[Y|g_0, e_1, c]}{E[Y|g_0, e_0, c]} + 1 \right\} dP(g|c)$$

where $\kappa = \frac{E[Y|g_0, e_0, c]}{E[Y|g_0, e_0, c]}$. The proportion of the effect of E attributable to interaction is given by:

$$pAI_{G=g_0}(E) = \frac{\int \left\{ \frac{E[Y|g, e_1, c]}{E[Y|g_0, e_0, c]} - \frac{E[Y|g, e_0, c]}{E[Y|g_0, e_0, c]} - \frac{E[Y|g_0, e_1, c]}{E[Y|g_0, e_0, c]} + 1 \right\} dP(g|c)}{\left\{ \frac{E[Y|g_0, e_1, c]}{E[Y|g_0, e_0, c]} - 1 \right\} + \int \left\{ \frac{E[Y|g, e_1, c]}{E[Y|g_0, e_0, c]} - \frac{E[Y|g, e_0, c]}{E[Y|g_0, e_0, c]} - \frac{E[Y|g_0, e_1, c]}{E[Y|g_0, e_0, c]} + 1 \right\} dP(g|c)}.$$

Suppose first that E is continuous and G is binary, then this expression reduces to

$$pAI_{G=g_0}(E) = \frac{\left\{ \frac{E[Y|g_1, e_1, c]}{E[Y|g_0, e_0, c]} - \frac{E[Y|g_1, e_0, c]}{E[Y|g_0, e_0, c]} - \frac{E[Y|g_0, e_1, c]}{E[Y|g_0, e_0, c]} + 1 \right\} P(G = g_1|c)}{\left\{ \frac{E[Y|g_0, e_1, c]}{E[Y|g_0, e_0, c]} - 1 \right\} + \left\{ \frac{E[Y|g_1, e_1, c]}{E[Y|g_0, e_0, c]} - \frac{E[Y|g_1, e_0, c]}{E[Y|g_0, e_0, c]} - \frac{E[Y|g_0, e_1, c]}{E[Y|g_0, e_0, c]} + 1 \right\} P(G = g_1|c)}.$$

Under the logistic regression model with a rare outcome

$$\text{logit}\{P(Y = 1|G = g, E = e, C = c)\} = \gamma_0 + \gamma_1 g + \gamma_2 e + \gamma_3 eg + \gamma'_4 c, \quad (A1)$$

the proportion attributable to interaction is given by approximately by: $pAI_{G=g_0}(E) \approx$

$$\frac{\{e(g_1 - g_0)\gamma_1 + (e_1 - e_0)\gamma_2 + (g_1 e_1 - g_0 e_0)\gamma_3 - e(g_1 - g_0)\gamma_1 + (g_1 - g_0)e_0\gamma_3 - e(e_1 - e_0)\gamma_2 + (e_1 - e_0)g_0\gamma_3 + 1\}P(G = g_1|c)}{\{e(e_1 - e_0)\gamma_2 + (e_1 - e_0)g_0\gamma_3 - 1\} + \{e(g_1 - g_0)\gamma_1 + (e_1 - e_0)\gamma_2 + (g_1 e_1 - g_0 e_0)\gamma_3 - e(g_1 - g_0)\gamma_1 + (g_1 - g_0)e_0\gamma_3 - e(e_1 - e_0)\gamma_2 + (e_1 - e_0)g_0\gamma_3 + 1\}P(G = g_1|c)}.$$

Suppose now that G is continuous and normally distributed with mean

$$E[G|c] = \alpha_0 + \alpha'_1 c \quad (A2)$$

and variance σ^2 . Assuming a rare outcome, under logistic regression (A1) we have:

$$\begin{aligned} & \int \frac{E[Y|g, e, c]}{E[Y|g_0, e_0, c]} dP(g|c) \\ & \approx \int \exp\{(g - g_0)\gamma_1 + (e - e_0)\gamma_2 + (ge - g_0 e_0)\gamma_3\} dP(g|c) \\ & = \exp\{-g_0\gamma_1 + (e - e_0)\gamma_2 - g_0 e_0\gamma_3\} \int \exp\{g(\gamma_1 + e\gamma_3)\} dP(g|c) \\ & = \exp\{-g_0\gamma_1 + (e - e_0)\gamma_2 - g_0 e_0\gamma_3 + (\gamma_1 + e\gamma_3)(\alpha_0 + \alpha'_1 c) + \frac{1}{2}(\gamma_1 + e\gamma_3)^2 \sigma^2\} \end{aligned}$$

and thus the proportion attributable to interaction is: $pAI_{G=g_0}(E) =$

$$\begin{aligned} & \frac{\int \left\{ \frac{E[Y|g, e_1, c]}{E[Y|g_0, e_0, c]} - \frac{E[Y|g, e_0, c]}{E[Y|g_0, e_0, c]} - \frac{E[Y|g_0, e_1, c]}{E[Y|g_0, e_0, c]} + 1 \right\} dP(g|c)}{\left\{ \frac{E[Y|g_0, e_1, c]}{E[Y|g_0, e_0, c]} - 1 \right\} + \int \left\{ \frac{E[Y|g, e_1, c]}{E[Y|g_0, e_0, c]} - \frac{E[Y|g, e_0, c]}{E[Y|g_0, e_0, c]} - \frac{E[Y|g_0, e_1, c]}{E[Y|g_0, e_0, c]} + 1 \right\} dP(g|c)} \approx \\ & \frac{e^{-g_0\gamma_1 + (e_1 - e_0)\gamma_2 - g_0 e_0\gamma_3 + (\gamma_1 + e_1\gamma_3)(\alpha_0 + \alpha'_1 c) + \frac{1}{2}(\gamma_1 + e_1\gamma_3)^2 \sigma^2} - e^{-g_0\gamma_1 - g_0 e_0\gamma_3 + (\gamma_1 + e_0\gamma_3)(\alpha_0 + \alpha'_1 c) + \frac{1}{2}(\gamma_1 + e_0\gamma_3)^2 \sigma^2}}{e^{-g_0\gamma_1 + (e_1 - e_0)\gamma_2 - g_0 e_0\gamma_3 + (\gamma_1 + e_1\gamma_3)(\alpha_0 + \alpha'_1 c) + \frac{1}{2}(\gamma_1 + e_1\gamma_3)^2 \sigma^2} - e^{-g_0\gamma_1 - g_0 e_0\gamma_3 + (\gamma_1 + e_0\gamma_3)(\alpha_0 + \alpha'_1 c) + \frac{1}{2}(\gamma_1 + e_0\gamma_3)^2 \sigma^2}} \\ & + \frac{-e^{(e_1 - e_0)\gamma_2 + (e_1 - e_0)g_0\gamma_3 + 1}}{e^{-g_0\gamma_1 + (e_1 - e_0)\gamma_2 - g_0 e_0\gamma_3 + (\gamma_1 + e_1\gamma_3)(\alpha_0 + \alpha'_1 c) + \frac{1}{2}(\gamma_1 + e_1\gamma_3)^2 \sigma^2} - e^{-g_0\gamma_1 - g_0 e_0\gamma_3 + (\gamma_1 + e_0\gamma_3)(\alpha_0 + \alpha'_1 c) + \frac{1}{2}(\gamma_1 + e_0\gamma_3)^2 \sigma^2}}. \end{aligned}$$

2.2. Proportion of a Joint Effect Attributable to Either Exposure Alone and to Interaction

Let $RR_{g_1e_1} = \frac{E[Y|g_1,e_1,c]}{E[Y|g_0,e_0,c]}$. For the three-way decomposition of the joint excess relative risk of both exposures, $RR_{g_1e_1} - 1$, we have the decomposition:

$$(RR_{g_1e_1} - 1) = (RR_{g_1e_0} - 1) + (RR_{g_0e_1} - 1) + (RR_{g_1e_1} - RR_{g_1e_0} - RR_{g_0e_1} + 1).$$

Under the logistic regression model with a rare outcome

$$\text{logit}\{P(Y = 1|G = g, E = e, C = c)\} = \gamma_0 + \gamma_1g + \gamma_2e + \gamma_3eg + \gamma_4'c,$$

the proportions of the joint excess relative risk of both exposures due to each of the exposures considered alone and due to interaction can be estimated approximately by:

$$\begin{aligned} \frac{RR_{g_1e_0} - 1}{RR_{g_1e_1} - 1} &\approx \frac{e^{(g_1-g_0)\gamma_1+(g_1-g_0)e_0\gamma_3} - 1}{e^{(g_1-g_0)\gamma_1+(e_1-e_0)\gamma_2+(g_1e_1-g_0e_0)\gamma_3} - 1} \\ \frac{RR_{g_0e_1} - 1}{RR_{g_1e_1} - 1} &\approx \frac{e^{(e_1-e_0)\gamma_2+(e_1-e_0)g_0\gamma_3} - 1}{e^{(g_1-g_0)\gamma_1+(e_1-e_0)\gamma_2+(g_1e_1-g_0e_0)\gamma_3} - 1} \\ \frac{(RR_{g_1e_1} - RR_{g_1e_0} - RR_{g_0e_1} + 1)}{RR_{g_1e_1} - 1} &\approx \frac{\{e^{(g_1-g_0)\gamma_1+(e_1-e_0)\gamma_2+(g_1e_1-g_0e_0)\gamma_3} - e^{(g_1-g_0)\gamma_1+(g_1-g_0)e_0\gamma_3} - e^{(e_1-e_0)\gamma_2+(e_1-e_0)g_0\gamma_3} + 1\}}{e^{(g_1-g_0)\gamma_1+(e_1-e_0)\gamma_2+(g_1e_1-g_0e_0)\gamma_3} - 1}. \end{aligned}$$

2.3. SAS Code to Implement Proportion of a Total Effect Attributable to Interaction

Although we could obtain analytic standard errors for the expressions in Section 2.1 using the delta, the formulae would be very involved. The SAS procedure `proc nlmixed`, can however, carry out standard error computations for these expressions.

To estimate the proportion of the total effect of E on binary outcome Y due to E when G is fixed to g_0 and the proportion due to interaction when G is binary, and logistic regression model (A1) is used, one can use the code below. Suppose we have a dataset named 'mydata' with outcome variable 'y', exposure variables 'e' and 'g' and three covariates 'c1', 'c2' and 'c3'. If there were more or fewer covariates the user would have to modify the second and fourth lines of the code below to include these covariates.

The user must input in the third line of code the two levels of G ('g1=' and 'g0=') and the two levels of E ('e1=' and 'e0=') that are being compared. The user must also input in the third line of the code the prevalence of the exposure G ('pg=') conditional on $C = c$ (or use the marginal prevalence of G as a summary). In a case-control study, these prevalences should be computed only among the controls. For the standard error to be valid it is assumed that the prevalence of G is known; alternatively, standard errors and confidence interval can be interpreted as that for the proportion attributable to interaction in a population which had the same underlying risk ratios as the sample in question, but had a prevalence of G equal to the prevalence of G in the sample.

The output will include the proportion of the total effect of E that is attributable to interaction, along with a 95% confidence interval; the remaining proportion is that attributable to E when G is set to g_0 .

```
proc nlmixed data=mydata;
parms b0=1 b1=0 b2=0 b3=0 bc1=0 bc2=0 bc3=0;
```

```

g1=1; g0=0; e1=1; e0=0; pg=0.5;
p_y=(1+exp(-(b0 + b1*G + b2*E + b3*G*E + bc1*C1 + bc2*C2 + bc3*C3)))*-1;
ll_y= y*log (p_y)+(1-y)*log(1-p_y);
model Y ~general(ll_y);
estimate 'PAI_E' (exp((g1-g0)*b1+(e1-e0)*b2+(g1*e1-g0*e0)*b3)-exp((g1-g0)*b1+(g1-g0)*e0*b3)
-exp((e1-e0)*b2+(e1-e0)*g0*b3)+1)*pg
/ ( ( exp((e1-e0)*b2+(e1-e0)*g0*b3) - 1) + (exp((g1-g0)*b1+(e1-e0)*b2+(g1*e1-g0*e0)*b3)
-exp((g1-g0)*b1+(g1-g0)*e0*b3)-exp((e1-e0)*b2+(e1-e0)*g0*b3)+1) *pg);
run;

```

To estimate the proportion of the total effect of E on binary outcome Y due to E when G is fixed to g_0 and the proportion due to interaction when G is continuous, and logistic regressions models (A1) and (A2) are used, one can use the code below. Suppose we have a dataset named 'mydata' with outcome variable 'd', exposure variables 'e' and 'g' and three covariates 'c1', 'c2' and 'c3'. If there were more or fewer covariates the user would have to modify the second, third, fourth and fifth lines of the code below to include these covariates.

The user must input in the third line of code the two levels of G ('g1=' and 'g0=') and the two levels of E ('e1=' and 'e0=') that are being compared. The user must also input in the third line of the code the value of the covariates C at which the proportion attributable to interaction is to be calculated ('cc1=', 'cc2' and 'cc3='). Alternatively the mean value of these covariates in the sample could be inputted on this line as a summary measure (in a case-control study, these means should be computed only among the controls).

The output will include the proportion of the total effect of E that is attributable to interaction, along with a 95% confidence interval; the remaining proportion is that attributable to E when G is set to g_0 .

```

proc nlmixed data=mydata;
parms b0=1 b1=0 b2=0 b3=0 bc1=0 bc2=0 bc3=0 a0=0 ac1=0 ac2=0 ac3=0 ss_g=1;

2.4. SAS Code to Implement Proportion of a Joint Effect Attributable to Either Exposure Alone and to Interaction

To estimate the proportion of the joint effect of both exposures on binary outcome Y due to each exposure alone and due to interaction, when logistic regression model (A1) is used, one can use the code below. We again suppose we have a dataset named 'mydata' with outcome variable 'y', exposure variables 'e' and 'g' and three covariates 'c1', 'c2' and 'c3'. If there were more or fewer covariates the user would have to modify the second and fourth lines of the code below to include these covariates.

The user must input in the third line of code the two levels of G ('g1=' and 'g0=') and the two levels of E ('e1=' and 'e0=') that are being compared. The output gives the proportions due to G alone, the proportion due to E alone, and the proportion due to the interaction; 95% confidence intervals are also given for these three proportions. The three proportions will sum to 100%. The decomposition applies even if one of the exposures affects the other.

```
proc nlmixed data=mydata;
parms b0=1 b1=0 b2=0 b3=0 bc1=0 bc2=0 bc3=0;
g1=1; g0=0; e1=1; e0=0;
p_y=(1+exp(-(b0 + b1*G + b2*E + b3*G*E + bc1*C1 + bc2*C2 + bc3*C3)))*-1;
ll_y= y*log (p_y)+(1-y)*log(1-p_y);
model Y ~general(ll_y);
estimate 'PaG' (exp((g1-g0)*b1+(g1-g0)*e0*b3) - 1) / (exp((g1-g0)*b1+(e1-e0)*b2+(g1*e1-g0*e0)*b3) - 1);
estimate 'PaE' (exp((e1-e0)*b2+(e1-e0)*g0*b3) - 1) / (exp((g1-g0)*b1+(e1-e0)*b2+(g1*e1-g0*e0)*b3) - 1);
estimate 'Pa_INT' (exp((g1-g0)*b1+(e1-e0)*b2+(g1*e1-g0*e0)*b3)
-exp((g1-g0)*b1+(g1-g0)*e0*b3)-exp((e1-e0)*b2+(e1-e0)*g0*b3)+1)
/(exp((g1-g0)*b1+(e1-e0)*b2+(g1*e1-g0*e0)*b3) - 1);
run;
```

3. Continuous Outcomes and Binary or Continuous Exposures

3.1. Proportion of a Total Effect Attributable to Interaction

As discussed in the Appendix to the text, for continuous exposures, when the effect of E on Y is unconfounded conditional on (C, G) then the total effect of E on Y , $E[Y_{e1}|c] - E[Y_{e0}|c]$, could be decomposed into two components as: $E[Y_{e1}|c] - E[Y_{e0}|c]$

$$= E[Y|g_0, e_1, c] - E[Y|g_0, e_0, c] + \int \{E[Y|g, e_1, c] - E[Y|g, e_0, c] - E[Y|g_0, e_1, c] + E[Y|g_0, e_0, c]\} dP(g|c).$$

Under the linear model

$$E[Y|G = g, E = e, C = c] = \alpha_0 + \alpha_1 g + \alpha_2 e + \alpha_3 eg + \alpha'_4 c, \quad (\text{A3})$$

these two components are:

$$\begin{aligned} E[Y|g, e_1, c] - E[Y|g, e_0, c] &= (\alpha_2 + g\alpha_3)(e_1 - e_0) \\ \int \{E[Y|g, e_1, c] - E[Y|g, e_0, c] - E[Y|g_0, e_1, c] + E[Y|g_0, e_0, c]\} dP(g|c) &= \alpha_3 \{E[G|c] - g_0\}(e_1 - e_0) \end{aligned}$$

and the proportion due to interaction is then $\frac{\alpha_3 \{E[G|c] - g_0\}}{(\alpha_2 + \alpha_3 E[G|c])}$.

This decomposition above marginalized over the distribution $P(c)$ gives: $E[Y_{e1}] - E[Y_{e0}]$

$$= \int \{E[Y|g_0, e_1, c] - E[Y|g_0, e_0, c]\} dP(c) + \int \{E[Y|g, e_1, c] - E[Y|g, e_0, c] - E[Y|g_0, e_1, c] + E[Y|g_0, e_0, c]\} dP(g, c)$$

and under model (A3) the components are:

$$\begin{aligned} E[Y|g, e_1, c] - E[Y|g, e_0, c] &= (\alpha_2 + g\alpha_3)(e_1 - e_0) \\ \int \{E[Y|g, e_1, c] - E[Y|g, e_0, c] - E[Y|g_0, e_1, c] + E[Y|g_0, e_0, c]\} dP(g|c) &= \alpha_3 \{E[G] - g_0\}(e_1 - e_0) \end{aligned}$$

and the proportion due to interaction is then $\frac{\alpha_3\{E[G]-g_0\}}{(\alpha_2+\alpha_3E[G])}$. In section 3.3 SAS code is given for this latter decomposition.

3.2. Proportion of a Joint Effect Attributable to Either Exposure Alone and to Interaction

As also discussed in the Appendix to the text, if the joint effects of G and E are unconfounded conditional on C we can empirically decompose the joint effects of both exposures combined as follows:

$$\begin{aligned} E[Y|g_1, e_1, c] - E[Y|g_0, e_0, c] &= \{E[Y|g_1, e_0, c] - E[Y|g_0, e_0, c]\} + \{E[Y|g_0, e_1, c] - E[Y|g_0, e_0, c]\} \\ &\quad + \{E[Y|g_1, e_1, c] - E[Y|g_1, e_0, c] - E[Y|g_0, e_1, c] + E[Y|g_0, e_0, c]\}. \end{aligned}$$

We can then also compute the proportion of the joint effect due G alone as $\frac{E[Y|g_1, e_0, c] - E[Y|g_0, e_0, c]}{E[Y|g_1, e_1, c] - E[Y|g_0, e_0, c]}$, due to E alone as $\frac{E[Y|g_0, e_1, c] - E[Y|g_0, e_0, c]}{E[Y|g_1, e_1, c] - E[Y|g_0, e_0, c]}$, and due to their interaction as $\frac{E[Y|g_1, e_1, c] - E[Y|g_1, e_0, c] - E[Y|g_0, e_1, c] + E[Y|g_0, e_0, c]}{E[Y|g_1, e_1, c] - E[Y|g_0, e_0, c]}$.

On a difference scale, under the linear model

$$E[Y|G = g, E = e, C = c] = \alpha_0 + \alpha_1 g + \alpha_2 e + \alpha_3 eg + \alpha_4' c,$$

these three proportions are given by:

$$\begin{aligned} \frac{E[Y|g_1, e_0, c] - E[Y|g_0, e_0, c]}{E[Y|g_1, e_1, c] - E[Y|g_0, e_0, c]} &= \frac{(\alpha_1 + \alpha_3 e_0)(g_1 - g_0)}{\alpha_1(g_1 - g_0) + \alpha_2(e_1 - e_0) + \alpha_3(g_1 e_1 - g_0 e_0)} \\ \frac{E[Y|g_0, e_1, c] - E[Y|g_0, e_0, c]}{E[Y|g_1, e_1, c] - E[Y|g_0, e_0, c]} &= \frac{(\alpha_2 + \alpha_3 g_0)(e_1 - e_0)}{\alpha_1(g_1 - g_0) + \alpha_2(e_1 - e_0) + \alpha_3(g_1 e_1 - g_0 e_0)} \\ \frac{E[Y|g_1, e_1, c] - E[Y|g_1, e_0, c] - E[Y|g_0, e_1, c] + E[Y|g_0, e_0, c]}{E[Y|g_1, e_1, c] - E[Y|g_0, e_0, c]} &= \frac{\alpha_3(g_1 e_1 - g_1 e_0 - g_0 e_1 + g_0 e_0)}{\alpha_1(g_1 - g_0) + \alpha_2(e_1 - e_0) + \alpha_3(g_1 e_1 - g_0 e_0)}. \end{aligned}$$

3.3. SAS Code to Implement Proportion of a Total Effect Attributable to Interaction

To estimate the proportion of the total effect of E on continuous outcome Y due to E when G is fixed to g_0 and the proportion due to interaction, and logistic regression model (A3) is used, one can use the code below. Suppose we have a dataset named 'mydata' with outcome variable 'y', exposure variables 'e' and 'g' and three covariates 'c1', 'c2' and 'c3'. If there were more or fewer covariates the user would have to modify the second and fourth lines of the code below to include these covariates.

The user must input in the third line of code the level g_0 to which G will be fixed ('g0=') when carrying out the decomposition of the total effect of E into the proportion due to E when G is fixed to g_0 and the proportion due to interaction when G . The user must also input in the third line of the code the mean value of G in the population ('exg='). For the standard error to be valid it is assumed that the mean of G is known; alternatively, standard errors and confidence interval can be interpreted as that for the proportion attributable to interaction in a population which had the same underlying effects as the sample in question, but had a mean of G equal to the mean of G in the sample.

The output will include the proportion of the total effect of E that is attributable to interaction, along with a 95% confidence interval; the remaining proportion is that attributable to E when G is set to g_0 .

```

proc nlmixed data=mydata;
parms b0=0 b1=0 b2=0 b3=0 bc1=0 bc2=0 bc3=0 ss_y=1;
g0=0; exg=0.5;
mu_y = b0 + b1*G + b2*E + b3*G*E + bc1*C1 + bc2*C2 + bc3*C3;
ll_y=-((y-mu_y)**2)/(2*ss_y)-0.5*log(ss_y);
model Y ~general(ll_y);
estimate 'PAI_E' (b3*exg-g0)/(b2+b3*exg);
run;

```

3.4. SAS Code to Implement Proportion of a Joint Effect Attributable to Either Exposure Alone and to Interaction

To estimate the proportion of the joint effect of both exposures on continuous outcome Y due to each exposure alone and due to interaction, when logistic regression model (A3) is used, one can use the code below. We again suppose we have a dataset named 'mydata' with outcome variable 'y', exposure variables 'e' and 'g' and three covariates 'c1', 'c2' and 'c3'. If there were more or fewer covariates the user would have to modify the second and fourth lines of the code below to include these covariates.

The user must input in the third line of code the two levels of G ('g1=' and 'g0=') and the two levels of E ('e1=' and 'e0=') that are being compared. The output gives the proportions due to G alone, the proportion due to E alone, and the proportion due to the interaction; 95% confidence intervals are also given for these three proportions. The three proportions will sum to 100%. The decomposition applies even if one of the exposures affects the other.

```

proc nlmixed data=mydata;
parms b0=0 b1=0 b2=0 b3=0 bc1=0 bc2=0 bc3=0 ss_y=1;
g1=1; g0=0; e1=1; e0=0;
mu_y = b0 + b1*G + b2*E + b3*G*E + bc1*C1 + bc2*C2 + bc3*C3;
ll_y=-((y-mu_y)**2)/(2*ss_y)-0.5*log(ss_y);
model Y ~general(ll_y);
estimate 'PaG' (b1+b3*e0)*(g1-g0)/( b1*(g1-g0) + b2*(e1-e0) + b3*(g1*e1-g0*e0) );
estimate 'PaE' (b2+b3*g0)*(e1-e0)/( b1*(g1-g0) + b2*(e1-e0) + b3*(g1*e1-g0*e0) );
estimate 'Pa_INT' b3*(g1*e1-g1*e0-g0*e1+g0*e0)/( b1*(g1-g0) + b2*(e1-e0) + b3*(g1*e1-g0*e0) );
run;

```
