SUMMARY: Collection of functional data is becoming increasingly common including longitudinal observations in many studies. For example, we use magnetic resonance (MR) spectra collected over a period of time from late stage HIV patients. MR spectroscopy (MRS) produces a spectrum which is a mixture of metabolite spectra, instrument noise and baseline profile. Analysis of such data typically proceeds in two separate steps: feature extraction and regression modeling. In contrast, a recently-proposed approach, called partially empirical eigenvectors for regression (PEER) (Randolph, Harezlak and Feng, 2012), for functional linear models incorporates a priori knowledge via a scientifically-informed penalty operator in the regression function estimation process. We extend the scope of PEER to the longitudinal setting with continuous outcomes and longitudinal functional covariates. The method presented in this paper: 1) takes into account external information; and 2) allows for a time-varying regression function. In the proposed approach, we express the time-varying regression function as linear combination of several time-invariant component functions; the time dependence enters into the regression function through their coefficients. The estimation procedure is easy to implement due to its mixed model equivalence. We derive the precision and accuracy of the estimates and discuss their connection with the generalized singular value decomposition. Real MRS data and simulations are used to illustrate the concepts.

KEY WORDS: Functional data analysis, longitudinal data, mixed model, structured penalty, generalized singular value decomposition.

This paper has been submitted for consideration for publication in *Biometrics*

1. Introduction

Technological advancements and increased availability of storage of large datasets have allowed for the collection of functional data as part of time-course or longitudinal studies. In the cross-sectional setting, there have been many proposed methods for estimating a regression function in a so-called functional linear model (fLM). This function is a functional (continuous) analogue of a vector of (discrete) regression coefficients; it connects the scalar response, y to a functional covariate, $w \equiv w(s)$. Although these models have recently been well studied, extensions to longitudinally-collected functions have not received much attention. A recently-proposed approach called longitudinal penalized functional regression (LPFR) approach extends cross-sectional fLM to a longitudinal setting by incorporating subject-specific random intercepts (Goldsmith et al., 2012). One of the key assumption in LPFR is that the regression function remains constant over time. Due to this restrictive assumption, LPFR is not suited for situations in which the association between the functional predictors and scalar response may evolve over time. In this manuscript, we propose a technique that extends the analysis of functional linear models by relating scalar outcomes to functional predictors, both observed longitudinally, and allows the estimation of a time-varying regression function.

The method fits into a generalized ridge regression framework by imposing a scientifically-informed quadratic penalty term into the estimation process. The resulting estimate is a function that is represented by a set of “partially empirical” eigenvectors that arise from a joint eigen-basis decomposition of the predictor functions and the penalty term; see (Randolph, Harezlak and Feng, 2012). The extension of this framework to the longitudinal setting has two major advantages: 1) the regression function is allowed to vary over time; and 2) external or a priori information about the structure of the regression function can be incorporated directly

into the estimation process. We formulate the estimation procedure within a mixed-model framework making the method computationally efficient and easy to implement.

Ramsay and Dalzell (1991) introduced the term functional data analysis (FDA) in the statistical literature. The cross-sectional fLM with scalar response can be stated as follows (see e.g., Yao and Müller, 2010)

$$E(y|W) = \mu_y + \int_{\Omega} W(s)\gamma(s)ds$$

where μ_y is the mean of y , Ω denotes the domain of the predictor functions $W(s)$, $s \in \Omega$, and $\gamma(s)$ is a square integrable function that models the linear relationship between the functional predictors and scalar response. We will assume that $W(\cdot)$ denotes a mean-centered function ($E[W(s)] = 0$ for almost all $s \in \Omega$). As there is no unique $\gamma(\cdot)$ that solves this equation, additional regularization or constraint is required. Typically, some form of smoothness is imposed on $\gamma(\cdot)$, one approach being to expand both regression function $\gamma(\cdot)$ and predictor function $W(\cdot)$ in terms of a set of spline basis functions such as B-splines and then obtain the regularized estimate of $\gamma(\cdot)$ (Ramsay and Silverman, 1997). Another approach is to express the regression function $\gamma(\cdot)$ in terms of the orthonormal eigenfunctions of covariance of $W(\cdot)$ using Karhunen-Loève (K-L) basis expansion (see e.g., Müller, 2005). A third approach is to combine the above two approaches, known as penalized functional regression (PFR) approach (Goldsmith et al., 2011). In PFR approach, a spline basis is used to represent the regression function and a basis of eigenfunctions from the set of predictors is used to represent each $W(\cdot)$. Another approach is to use wavelet basis, instead of eigenfunctions, to represent the predictor functions (Morris and Carroll, 2006).

Here we adopt an approach by Randolph, Harezlak and Feng (2012) which does not begin by explicitly projecting onto a pre-specified basis of functions. Instead, prior information about functional structure is incorporated into the estimation process by way of a penalty operator.

“Partially empirical eigenvectors for regression” (PEER) approach exploits the fact that, in the familiar framework of penalized least-squares regression, the estimate arises from a set of basis functions that is determined jointly by the covariance (empirical spatial structure) and the penalty (imposed structure). This naturally extends ridge regression (noninformative structure) and smoothing penalties such as a second-derivative penalty (smooth regression function assumption). In this paper, we extend the scope of the PEER approach to the longitudinal setting in a manner that allows the estimated regression function $\gamma \equiv \gamma(t, \cdot)$ to vary with time.

The problem we address involves repeated observations from each of N subjects. At each observation time, t , we collect data on a scalar response variable, y , and a (idealized) predictor function, $W(\cdot)$. We are interested in longitudinal regression models of the following form:

$$y_t = x_t^\top \beta + \int_{\Omega} W_t(s) \gamma(t, s) ds + \epsilon_t \quad (1)$$

Here $\gamma(t, \cdot)$ denotes the regression function at time t , x_t is a vector of scalar-valued (non-functional) predictors. In a similar spirit to that of a linear mixed model with time-related slope for longitudinal data, we assume that $\gamma(t, \cdot)$ can be decomposed into several time-invariant component functions; e.g., $\gamma(t, \cdot) = \gamma_0(\cdot) + t \gamma_1(\cdot)$.

The recently proposed LPFR approach assumes the regression function in (1) is independent of time and proceeds in three steps: uses a truncated set of K-L vectors to represent the predictor functions; expresses the regression function using a spline basis; and fits the longitudinal model using an equivalent mixed-model framework that incorporates subject-specific random effects. In contrast, we model the coefficient function $\gamma(t, \cdot)$ as a time-dependent combination of several time-invariant component functions, $\{\gamma_d(\cdot)\}_{d=0}^D$, each of which is estimated via a penalty operator that is informed by the structure of the data or a scientific question.

Our work is motivated by a study in which magnetic resonance (MR) spectra have been

collected longitudinally from late stage HIV patients (Harezlak et al., 2011). The observed spectra from MR spectroscopy (MRS) are a mixture of pure metabolite spectra, baseline profile and instrument noise.

Pure metabolite spectra provide information about the spatial structure of the observed spectra and consequently can be used to inform the regression function. Figure 1 shows the baseline MR spectra, $W(\cdot)$, from a brain region called basal ganglia for 114 subjects and also plots nine pure metabolite spectra. We are interested in studying the association of y with the metabolite concentrations. It is natural that the spatial structure (shape) of these metabolite spectra should inform the process of estimating the relationship between y and $W(\cdot)$; i.e., the subspace spanned by the functional structure of the pure metabolite spectra may be more informative than structures such as B-spline or cosine functions that are “external” to the problem. Therefore, the statistical methodology applied in this paper estimates γ focusing on a subspace that is spanned by a basis of generalized singular vectors that arise jointly from the predictors, $W(\cdot)$, and the metabolite spectra.

[Figure 1 about here.]

The cross-sectional fLM with scalar response has been a focus of various investigations (Ramsay and Silverman, 1997; Faraway, 1997; Fan and Zhang, 2000; Cardot, Ferraty and Sarda, 1999, 2003; Cai and Hall, 2006; Cardot et al., 2007; Reiss and Ogden, 2009). Some of these methods estimate regression functions in two steps. For example, principal components regression (PCR) estimates of the regression function are obtained first and then these PCR estimates are projected onto a B-spline basis (Cardot, Ferraty and Sarda, 2003) or vice-versa; i.e., PCR fitting is performed only after projection onto B-splines (Reiss and Ogden, 2009). Extensions of fLM have been made towards generalized linear model with functional predictors (James, 2002; Müller and Stadtmüller, 2005) and quadratic functional regression (Yao and

Müller, 2010). Another class of models, known as Functional Analysis of Variance (FANOVA), decompose repetitively-observed functional predictors into several (fixed and random) groups and subject-specific component functions (Brumback and Rice, 1998; Guo, 2002; Di et al., 2009; Greven et al., 2011). However, it is important to distinguish our work from FANOVA methods which do not relate functional predictor(s) to the scalar response in longitudinal set up, the way we did it in this paper. To our knowledge, LPFR (Goldsmith et al., 2012) is the only published method addressing regression estimation in the longitudinal functional predictor framework.

Section 2 establishes notation and specifics on the longitudinal functional model considered in this paper. In the applications, we employ a decomposition-based penalty and this is review in Section 3.3. First, in Section 3.1, the concept of a generalized ridge estimate (or Tikhonov-Phillips estimate, Tikhonov (1963), Phillips (1962)) is discussed while Section 3.2 shows that under weak assumptions, our longitudinal generalized ridge estimate, along with its bias and precision, can be obtained in terms of generalized singular (GS) vectors. These estimates can be obtained as best linear unbiased predictors (BLUP) through mixed model equivalence and this is discussed in Section 4.1. Expressions for precision are derived in Section 4.2.

Numerical illustrations are provided in Section 5. In particular, the simulation in Section 5.1 compares LPFR with the method proposed in this paper. The simulation in subsection 5.2 evaluates the influence of sample size and relative contribution of prior spatial information on the proposed method using a decomposition-based penalty. An application based on experimental data is also illustrated in section 6. The methods discussed in this paper have been implemented in the `refund` package (Crainiceanu et al., 2012) in R through the `peer()` and `lpeer()`. Throughout the presentation we consider a single functional predictor. However, the

proposed method has a natural extension to settings with more than one functional predictor and this is discussed in the last section.

2. Statistical Model

We consider $\Omega = [0, 1]$, a closed interval in $\mathbb{R}$ and let $W(\cdot)$ denotes a random function in $L^2(\Omega)$. Let $W_{it}(\cdot)$ denotes a functional predictor from the i^{th} subject ($i = 1, \dots, N$) at the t^{th} timepoint ($t = t_1, \dots, t_{n_i}$). Technically, an observed predictor arises as a discretized sampling from an idealized function, and we will assume that each observed predictor is sampled equally at p locations, $s_1, \dots, s_p \in [0, 1]$, with sampling that is appropriately regular and dense enough to capture informative spatial structure, as seen, for instance, in the MRS data in Section 6. Let $w_{it} := [w_{it}(s_1), \dots, w_{it}(s_p)]^\top$ be the $p \times 1$ vector of values sampled from the realized function $W_{it}(\cdot)$. Then, the observed data are of the form $\{y_{it}; x_{it}; w_{it}\}$, where y_{it} is a scalar outcome, x_{it} is a $K \times 1$ column vector of measurements on K scalar predictors, and w_{it} is the sampled predictor from the i^{th} subject at time t . Denoting the true regression function at time t by $\gamma(t, \cdot)$, the longitudinal functional regression outcome model of interest is

$$y_{it} = x_{it}^\top \beta + \int_0^1 W_{it}(s) \gamma(t, s) ds + z_{it}^\top b_i + \epsilon_{it} \quad (2)$$

where, $\epsilon_{it} \sim N(0, \sigma_\epsilon^2)$ and b_i is the vector of r random effects pertaining to subject i and distributed as $N(0, \Sigma_{b_i})$. As usual we assume that z_{it} is a subset of x_{it} , ϵ_{it} and b_i are independent, ϵ_{it} and $\epsilon_{i't'}$ are independent whenever $i \neq i'$ or $t \neq t'$ or both, and b_i and $b_{i'}$ are independent if $i \neq i'$. Here $x_{it}^\top \beta$ is the standard fixed effect from K univariate predictors, $z_{it}^\top b_i$ is the standard random effect and $\int_0^1 W_{it}(s) \gamma(t, s) ds$ is the subject/time specific functional effect. We assume that $\gamma(t, \cdot) \in L^2(\Omega)$, for all t .

When the association between functional predictor and response changes over time, the regression function $\gamma(t, s)$ varies over both spatial and time domain. For example, $\gamma(t, s)$ may vary

linearly with time, $\gamma(t, s) = \gamma_0(s) + t\gamma_1(s)$, or quadratically, $\gamma(t, s) = \gamma_0(s) + t\gamma_1(s) + t^2\gamma_2(s)$. This is in a spirit similar to a linear mixed effects model with linear or quadratic time slope (see e.g., Fitzmaurice, Laird and Ware, 2004). In general, we assume that $\gamma(t, s)$ can be decomposed into several time-invariant component functions $\gamma_0(s), \dots, \gamma_D(s)$ as

$$\gamma(t, s) = \gamma_0(s) + f_1(t)\gamma_1(s) + \dots + f_D(t)\gamma_D(s)$$

where, $f_1, \dots, f_D$ are D prescribed linearly independent functions of t and $f_d(0) = 0$ for all d ; the time component t enters into $\gamma(t, s)$ through these terms.

At $t = 0$, $\gamma(t, s)$ reduces to $\gamma_0(s)$ and has the obvious interpretation of a baseline regression function pertaining to the sampling points s . When $D = 0$, $\gamma(t, s) \equiv \gamma_0(s)$ is independent of t , a situation considered by Goldsmith et al. (2012). In general, each f may be any function of t with $f(0) = 0$, e.g., $f(t) = t$ or $t \exp(t)$. We can rewrite the equation (2) as

$$y_{it} = x_{it}^\top \beta + \int_0^1 W_{it}(s) \{ \gamma_0(s) + f_1(t)\gamma_1(s) + \dots + f_D(t)\gamma_D(s) \} ds + z_{it}^\top b_i + \epsilon_{it}$$

In a PEER approach, the dependence of y_{it} on W_{it} is seen as a linear dependence on observations at p sampling points, w_{it} ; spatial (functional) structure is imposed directly into the estimation of $\gamma_d = [\gamma_d(s_1), \dots, \gamma_d(s_p)]^\top$, for $d = 0, \dots, D$. Combining all $n_\bullet = \sum_{i=1}^N n_i$ observations from the N subjects obtained across all time points, we express the model as

$$y = X\beta + W\gamma + Zb + \epsilon. \quad (3)$$

Here, $y = [y_{1t_1}, \dots, y_{1t_{n_1}}, \dots, y_{1t_N}, \dots, y_{Nt_{n_N}}]^\top$ is an $n_\bullet \times 1$ vector of all responses, $X = [x_{1t_1}^\top, \dots, x_{1t_{n_1}}^\top, \dots, x_{1t_N}^\top, \dots, x_{Nt_{n_N}}^\top]^\top$ is an $n_\bullet \times K$ design matrix pertaining to K univariate predictors, β be the associated coefficient vector, $\gamma = [\gamma_0^\top, \gamma_1^\top, \dots, \gamma_D^\top]^\top$ is a $(D+1)p \times 1$ vector of functional coefficients, W is the corresponding $n_\bullet \times (D+1)p$ design matrix. Further, b is the $rN \times 1$ vector of random effects and Z is the corresponding $n_\bullet \times rN$ design matrix. The

matrix W has the structure

$$W = \begin{bmatrix} W_1 \\ \vdots \\ W_N \end{bmatrix} \quad W_i = \begin{bmatrix} w_{it_1}^\top & f_1(t_1)w_{it_1}^\top & \cdots & f_D(t_1)w_{it_1}^\top \\ \vdots & \vdots & \ddots & \vdots \\ w_{it_{n_i}}^\top & f_1(t_{n_i})w_{it_{n_i}}^\top & \cdots & f_D(t_{n_i})w_{it_{n_i}}^\top \end{bmatrix}$$

3. Estimation of Parameters with a Penalty

The formal model in (2) is ill-posed and has no unique solution for γ . Common approaches to estimate a regression function in a fLM involve reducing dimension by projecting onto a subspace defined by a few K-L (empirical) eigenvectors or onto the span of a set of spline basis functions. Alternatively, our use of a generalized ridge penalty constrains the estimation of γ in the spatial (or s) dimension without preliminary smoothing or explicit dimension reduction. The process encourages structure of a particular type via the choice of penalty operator. In the longitudinal (or t) dimension, γ is more explicitly and severely constrained by the choice of $f_1, \dots, f_D$.

3.1 Generalized Ridge Estimate

The model of interest described in the previous section can be written as follows:

$$y = X\beta + W\gamma + \epsilon^* \quad (4)$$

where $\epsilon^* = Zb + \epsilon \sim N(0, V)$ and $V = Z\Sigma_b Z^\top + \sigma_\epsilon^2 I$. Further, assume L_d be the penalty operator for γ_d and λ_d^2 be the associated tuning parameter, $\forall d = 0, \dots, D$. Then the penalized estimates of β and γ can be obtained by minimizing

$$\|y - X\beta - W\gamma\|_{V^{-1}}^2 + \lambda_0^2 \|\gamma_0\|_{L_0^\top L_0}^2 + \cdots + \lambda_D^2 \|\gamma_D\|_{L_D^\top L_D}^2 \quad (5)$$

here we have used the notation $\|a\|_B^2 = a^\top B a$, where B is a symmetric, positive definite matrix. A generalized ridge estimate of β and γ based on minimizing the above expression is

obtained as (see e.g., Ruppert, Wand and Carroll, 2003, p. 66)

$$\begin{bmatrix} \hat{\beta} \\ \hat{\gamma} \end{bmatrix} = (C^\top V^{-1} C + D)^{-1} C^\top V^{-1} y \quad (6)$$

where, $C = [X \ W]$, $D = \text{blockdiag}\{0, L^\top L\}$ and $L = \text{blockdiag}\{\lambda_0 L_0, \dots, \lambda_D L_D\}$.

3.2 Connection with the GSVD

A PEER estimate and its mean squared error (MSE) can be expressed in terms of generalized singular (GS) vectors obtained through generalized singular value decomposition (GSVD) for the cross-sectional fLM with single functional predictor and no random effect Randolph, Harezlak and Feng (2012). For background on the GSVD and its computation, see Van-Loan (1976); Paige and Saunders (1981); Bjorck (1996); Golub and Van-Loan (1996). Here, we derive a similar expression for the generalized ridge estimate $\hat{\gamma}$ of the regression function in (6).

After some algebra, the generalized ridge estimate in (6) for γ can be expressed as

$$\hat{\gamma} = -A_1 X^\top V^{-1} y + A_2 W^\top V^{-1} y$$

where

$$A_1^\top = (X^\top V^{-1} X)^{-1} X^\top V^{-1} W [W^\top V^{-1} W + L^\top L - W^\top V^{-1} X (X^\top V^{-1} X)^{-1} X^\top V^{-1} W]^{-1}$$

$$A_2 = W^\top V^{-1} W + L^\top L - W^\top V^{-1} X (X^\top V^{-1} X)^{-1} X^\top V^{-1} W$$

When $X = 0$ (a situation without any scalar predictors) or $X^\top V^{-1} W = 0$ the generalized ridge estimation of γ can be put into a PEER estimation framework in terms of GS vectors, as discussed below.

With $X = 0$ or $X^\top V^{-1} W = 0$, the $\hat{\gamma}$ reduces to $[W^\top V^{-1} W + L^\top L]^{-1} W^\top V^{-1} y$. Moreover, in this case generalized ridge estimate of β becomes $[X^\top V^{-1} X]^{-1} X^\top V^{-1} y$. Now, if we transform $\tilde{W} := V^{-1/2} W$ and $\tilde{y} := V^{-1/2} y$, we can rewrite L as

$$L = \lambda_0 \text{blockdiag} \left\{ L_0, \frac{\lambda_1}{\lambda_0} L_1, \dots, \frac{\lambda_D}{\lambda_0} L_D \right\} = \lambda_0 L^s$$

Here, L^s can be interpreted as a scaled L where scaling is done for all the tuning parameters associated with the ‘longitudinal’ part of the regression function with respect to the ‘baseline’ tuning parameter.

Set $\tilde{p} = (D + 1)p$, let m denote the number of rows in L and set $c = \dim[\text{Null}(L)]$. Further, assume that $n_\bullet \leq m \leq \tilde{p} \leq m + n_\bullet$ and the rank of the $(n_\bullet + m) \times \tilde{p}$ matrix $[\tilde{W}^\top \quad (L^s)^\top]^\top$ is $\tilde{p}$. The following describes the GSVD of the pair $(\tilde{W}, L^s)$: there exist orthogonal matrices $\mathcal{U}$ and $\mathcal{V}$, a nonsingular $\mathcal{G}$ and diagonal matrices S and M such that Randolph, Harezlak and Feng (2012)

$$\tilde{W} = \mathcal{U}S\mathcal{G}^{-1} \quad S = [0 \quad S] \quad S = \text{blockdiag}\{S_1, \quad I_{\tilde{p}-m}\}$$

$$L^s = \mathcal{V}\mathcal{M}\mathcal{G}^{-1} \quad \mathcal{M} = [M \quad 0] \quad M = \text{blockdiag}\{I_{\tilde{p}-n_\bullet}, \quad M_1\}$$

Submatrices S_1 and M_1 have $\ell = n_\bullet + m - \tilde{p}$ diagonal entries ordered as

$$\begin{aligned} 0 < \sigma_1 \leq \sigma_2 \leq \cdots \leq \sigma_\ell < 1 \\ 0 > \mu_1 \geq \mu_2 \geq \cdots \geq \mu_\ell > 1 \end{aligned} \quad \text{where,} \quad \sigma_k^2 + \mu_k^2 = 1, \quad k = 1, \dots, \ell$$

Here, the columns $\{g_k\}$ of $\mathcal{G}$ are the GS vectors determined by the GSVD of the pair $(\tilde{W}, L^s)$.

Denote the columns of $\mathcal{U}$ and $\mathcal{V}$ by u_k and v_k , respectively. Now, it can be shown that

$$[W^\top V^{-1}W + L^\top L]^{-1}W^\top V^{-1} = [W^\top V^{-1}W + \lambda_0^2(L^s)^\top L^s]^{-1}W^\top V^{-1} = \mathcal{G}(\mathcal{S}^\top \mathcal{S} + \lambda_0^2 \mathcal{M}^\top \mathcal{M})^{-1} \mathcal{G}^\top \tilde{W}^\top V^{-1/2}$$

and consequently, $\hat{\gamma}$ can be expressed as

$$\hat{\gamma} = \mathcal{G}(\mathcal{S}^\top \mathcal{S} + \lambda_0^2 \mathcal{M}^\top \mathcal{M})^{-1} \mathcal{S}^\top \mathcal{U}^\top \tilde{y} = \sum_{k=\tilde{p}-n_\bullet+1}^{\tilde{p}-c} \frac{\sigma_k^2}{\sigma_k^2 + \lambda_0^2 \mu_k^2} \frac{1}{\sigma_k} u_k^\top \tilde{y} g_k + \sum_{k=\tilde{p}-c+1}^{\tilde{p}} u_k^\top \tilde{y} g_k$$

Further, the bias and variance can be expressed as

$$\begin{aligned} \text{Bias}[\hat{\gamma}] &= (I - W^\# W) \gamma = \mathcal{G}(\mathcal{S}^\top \mathcal{S} + \lambda_0^2 \mathcal{M}^\top \mathcal{M})^{-1} (\lambda_0^2 \mathcal{M}^\top \mathcal{M}) \mathcal{G}^{-1} \\ &= \sum_{k=1}^{\tilde{p}-n_\bullet} g_k \tilde{g}_k^\top \gamma + \sum_{k=\tilde{p}-n_\bullet+1}^{\tilde{p}-c} \frac{\lambda_0^2 \mu_k^2}{\sigma_k^2 + \lambda_0^2 \mu_k^2} g_k \tilde{g}_k^\top \gamma \end{aligned}$$

$$\text{Var}[\hat{\gamma}] = W^\# V (W^\#)^\top = \mathcal{G}(\mathcal{S}^\top \mathcal{S} + \lambda_0^2 \mathcal{M}^\top \mathcal{M})^{-1} \mathcal{S}^\top \mathcal{S} (\mathcal{S}^\top \mathcal{S} + \lambda_0^2 \mathcal{M}^\top \mathcal{M})^{-1} \mathcal{G}^\top$$

$$= \sum_{k=\tilde{p}-n_\bullet+1}^{\tilde{p}-c} \frac{\sigma_k^2}{(\sigma_k^2 + \lambda_0^2 \mu_k^2)^2} g_k g_k^\top + \sum_{k=\tilde{p}-c+1}^{\tilde{p}} g_k g_k^\top$$

where, $W^\# = [W^\top V^{-1}W + L^\top L]^{-1}W^\top V^{-1}$ and $\tilde{g}_k$ denotes the k th column of $\mathcal{G}^{-T} = (\mathcal{G}^{-1})^\top = (\mathcal{G}^\top)^{-1}$. Further, we can express bias as $[W^\top V^{-1}W + L^\top L]^{-1}L^\top L\gamma$ which means $\hat{\gamma}$ will be unbiased only when $\gamma \in \text{Null}(L)$.

For estimates obtained using this technique, the bias and variance can be expressed in terms of generalized singular vectors, provided the assumption of $X^\top V^{-1}W = 0$ applies. In this case, one can show that $\hat{\beta}$ is simply the generalized least squares estimate from the linear model $y = X\beta + \epsilon^*$, and $\hat{\gamma}$ is the generalized ridge estimate from $y = W\gamma + \epsilon^*$ with penalty L . That is, β is estimated as if $W\gamma$ were not present, and γ is estimated as if $X\beta$ were not present. The PEER estimate discussed in this section can be thought of as an extension of the estimation discussed in Randolph, Harezlak and Feng (2012) in two ways: we allow for a general covariance matrix V (for y) and we also extend the penalty operator to apply across multiply-defined domains, $L_0, \dots, L_D$.

3.3 Decomposition based penalty

Our goal is to estimate γ imposing some presumed functional structure. In other words, the aim is to supplement (not to smooth or otherwise alter) the predictor function with knowledge about spatial structure in a mathematically tractable way. A common approach to incorporate spatial structure into the functional regression model is to use the strongest structure from the predictors by considering only first few K-L vectors (Hall, Poskitt and Presnell, 2001; Cardot, Ferraty and Sarda, 2003). However, we will incorporate spatial structure through an informed choice of penalty operator as proposed by Randolph, Harezlak and Feng (2012).

Let $\gamma_d \equiv \gamma_{L_d, \lambda_d}$ be the estimate obtained from the penalty operator L_d and tuning parameter λ_d^2 , for each $d = 0, \dots, D$. For example, L_d may denote I_p (a ridge penalty) or a second-order derivative penalty (giving an estimate having continuous second derivative). Alterna-

tively, with prior knowledge about potentially-relevant structure in a regression function, a decomposition-based targeted penalty can be defined in terms of a subspace defined by such structure (Randolph, Harezlak and Feng, 2012). To be precise, if it is appropriate to impose scientifically-informed constraints on the “signal” being estimated by γ , this prior may be implemented by encouraging the estimate to be in or near a subspace, $\mathcal{Q} \subset L^2(\Omega)$.

Returning to our notation that reflects functional predictors observed at p sampling points, we represent $\mathcal{Q}$ by the range of a $p \times J$ matrix Q whose columns are $q_1, \dots, q_J$. Consider the orthogonal projection $P_Q = QQ^+$ onto the $\text{Range}(Q)$, where Q^+ is Moore-Penrose inverse of Q . Then a decomposition-based penalty is defined as

$$L_Q = \alpha_0 P_Q + \alpha_1 (I - P_Q) \quad (7)$$

for scalars α_0 and α_1 . To see how L_Q works, let $\tilde{\gamma}_d$ be any estimate of γ_d . When $\tilde{\gamma}_d \in Sp(Q)$, we have $L_Q \tilde{\gamma}_d = \alpha_0 \tilde{\gamma}_d$, but when $\tilde{\gamma}_d \notin Sp(Q)$, we have $L_Q \tilde{\gamma}_d = \alpha_1 \tilde{\gamma}_d$. The condition $\alpha_1 > \alpha_0$ imposes more penalty for $\tilde{\gamma}_d \notin P_Q$ compared to when $\tilde{\gamma}_d \in P_Q$. The weights α_1 and α_0 determine the relative strength of emphasizing $\mathcal{Q}$ in the estimation process. Note, in particular, that taking $\alpha_1 = \alpha_0$ results in a ridge estimate and that L_Q is invertible, provided α_1 and α_0 are nonzero. Analytical properties of estimates from this family of penalties have been discussed in Randolph, Harezlak and Feng (2012).

4. Mixed model representation

Estimates of β and γ obtained by minimizing the expression in equation (5) correspond to a generalized ridge estimate. In this section we aim to construct an appropriate mixed model that minimizes the expression in equation (5). In general, the penalty, L , is not required to be invertible but for simplicity this will be assumed here. The mixed model approach provides an automatic selection of tuning parameters. REML-based estimation of the tuning parameters

has been shown to perform as well as the other criteria and under certain conditions it is less variable than GCV-based estimation (Reiss and Ogden, 2009).

4.1 Estimation of parameters

Using Henderson's (1950) justification [21], one can show that the model $y = X\beta + W\gamma + \epsilon^*$ where, $\epsilon^* \sim N(0, V)$ and $\gamma_d \sim N(0, \frac{1}{\lambda_d^2}(L_d^\top L_d)^{-1})$, for each $d = 0, \dots, D$, minimizes the expression in equation (5) to obtain the BLUP. Thus the generalized ridge estimate of β and γ correspond to the BLUP from the following model:

$$y = X\beta + W^*\gamma^* + \epsilon$$

where, $W^* = [W \ Z]$, $\gamma^* = [\gamma^\top \ b^\top]^\top \sim N[0, \Sigma_{\gamma^*}]$ and $\epsilon \sim N(0, \sigma_\epsilon^2 I)$ with

$$\Sigma_{\gamma^*} = \text{blockdiag}\{(L^\top L)^{-1}, \ \Sigma_b\} \quad \Sigma_b = \text{blockdiag}\{\Sigma_{b_1}, \dots, \Sigma_{b_N}\}$$

This representation allows us to estimate fixed and functional predictors simply by fitting a linear mixed model (e.g., using the `lme()` of the `nlme` package in R or `PROC MIXED` in SAS).

4.2 Precision of Estimates

Our ridge estimate is the BLUP from equivalent mixed model, hence the variance of the estimate depends on whether the parameters are random or fixed. Randomness of γ is a device used to obtain the ridge estimate while ϵ and b in our case are truly random. With this argumentation, it can be advocated that variance of estimates to be conditional on γ , but not on b (Ruppert, Wand and Carroll, 2003). BLUP of β , γ and b can be expressed as (see e.g., Robinson, 1991; Ruppert, Wand and Carroll, 2003):

$$\tilde{\beta} = (X^\top V_1^{-1} X)^{-1} X^\top V_1^{-1} y \quad \tilde{\gamma} = (L^\top L)^{-1} W^\top V_1^{-1} (y - X\tilde{\beta}) \quad \tilde{b} = \Sigma_b Z^\top V_1^{-1} (y - X\tilde{\beta})$$

where, $V_1 = V + W(L^\top L)^{-1}W^\top$. $\tilde{\beta}$ is an unbiased estimator of β , but $\tilde{\gamma}$ is not unbiased. It is trivial to see that $\text{Cov}(y|\gamma) = V$. Thus, the variances of $\tilde{\beta}$ and $\tilde{\gamma}$, conditional on γ , are:

$$\text{Cov}(\tilde{\beta}|\gamma) = (X^\top V_1^{-1}X)^{-1}X^\top V_1^{-1}V V_1^{-1}X (X^\top V_1^{-1}X)^{-1}$$

$$\text{Cov}(\tilde{\gamma}|\gamma) = A_\gamma V A_\gamma^\top \quad A_\gamma = (L^\top L)^{-1}W^\top V_1^{-1}\{V_1 - X(X^\top V_1^{-1}X)^\top\}V_1^{-1}$$

To obtain the unconditional variance, we need to replace V by V_1 in the above expressions but this will overestimate the variance of the estimates. The expressions for predicted value of y and its variance are:

$$\tilde{y} = X\tilde{\beta} + W\tilde{\gamma} + Z\tilde{b} \quad \text{Cov}(\tilde{y}|\gamma) = A_y V A_y^\top$$

where,

$$A_y = [\{V_1 - WL^\top LW - Z\Sigma_b Z^\top\}^{-1}X (X^\top V^{-1}X)^{-1}X^\top V^{-1} + WL^\top LW^\top + Z\Sigma_b Z^\top]V_1^{-1}$$

Let, $T = [1 \ f_1(t) \ \cdots \ f_d(t)] \otimes I_K$. Then the discretized version of regression function at time t is $\gamma_{(t)} = [\gamma(t, s_1), \dots, \gamma(t, s_K)] = T\gamma$. Therefore, the estimate of $\gamma_{(t)}$ is $\tilde{\gamma}_{(t)} = T\tilde{\gamma}$ and the estimate of its variance is $T\text{Cov}(\tilde{\gamma}|\gamma)T^\top$.

5. Simulation

We present two simulation studies to evaluate the properties of the proposed method which we refer to as “LongPEER”. The first simulation study (Section 5.1) compares the performance of the LongPEER method with the LPFR approach. In the second simulation study, only the LongPEER method is considered. The purpose of the second simulation study is to evaluate the influence of sample size and the contribution of prior information about spatial structure (as determined by two different tuning parameters α_0 and α_1 in equation 7) on the LongPEER estimate. In both the simulation studies, the simulated predictor functions resemble the MRS data. All results summarized in this section are based on 100 simulated samples.

For each subject and visit, predictor functions were simulated independently. Predictor functions are “bumpy” curves with bumps at some prespecified locations. White noise was added to the predictor functions to account for the instrumental measurement noise. Bumpy regression functions were generated with bumps at some (but, not all) of the bump locations of the predictor function. For the simulation in Section 5.1, the regression function is assumed to be independent of time, whereas it varies with time in simulation in Section 5.2. For both the predictor and regression functions, 100 equispaced sampling points in $[0,1]$ are used.

For the decomposition based penalty, the matrix L_d matrix is defined as follows: 1) select the discretized functions $q_j, j = 1, \dots, J$ spanning the “non-penalized-subspace” and 2) compute $L_d = QQ^+$, where $Q = \text{col}[q_1, \dots, q_J]$. Vectors q_j are discretized functions defined to be zero except at one bump corresponding to a region in the simulated predictor functions. For ridge and second-order penalties, the matrices L_d are defined as I and $\mathcal{D}^2$, respectively, where $\mathcal{D}^2 = [d_{i,j}]$ is a square matrix with entries $d_{i,i} = d_{i,i+2} = 1$, $d_{i,i+1} = -2$ and $d_{i,j} = 0$ otherwise.

Estimation error was summarized in terms of the mean squared error (MSE) of the estimated regression function defined as $\|\gamma - \tilde{\gamma}\|^2$, where $\tilde{\gamma}$ denotes the estimate of γ . Further, MSE was decomposed into the trace of the variance and squared norm of bias. We also calculated sum of squares of prediction error (SSPE) as $\|y - \tilde{y}\|^2$, where $\tilde{y}$ denotes the estimate of y . The estimates based on the proposed methods, including the LongPEER estimate, were obtained as BLUPs from the mixed model formulation described in Section 4.1.

5.1 Comparison with LPFR

As previously stated, LPFR estimates a regression function that does not vary with time. Therefore, in the first set of simulations, we generated the outcomes using a time-invariant regression function (i.e., $\gamma(t, s) = \gamma_0(s)$, for all t). The following model was used to generate

the outcome data:

$$y_{it} = \beta_0 + \int_0^1 W_{it}(s)\gamma_0(s)ds + b_i + \epsilon_{it}, \quad i = 1, \dots, 100, \quad (8)$$

$$\text{where} \quad \gamma_0(s) = \sum_{h \in H_{\gamma_0}} a_{0h} \exp \left[-2500 * \left(\frac{h-s}{100} \right)^2 \right]$$

The bumpy predictor functions were generated from the following equation

$$w_{it}(s) = \sum_{h \in H_1} (\xi_{1h} + c_{1h}) \exp \left[-2500 * \left(\frac{s-h}{100} \right)^2 \right] + \sum_{h \in H_2} (\xi_{2h} + c_{2h}) \exp \left[-1000 * \left(\frac{s-h}{100} \right)^2 \right]$$

$$+ (\xi_{31} + 0.9) \exp \left[-1000 * \xi_{32} \left(\frac{s-50}{100} \right)^2 \right],$$

[Table 1 about here.]

where c_{1h} , c_{2h} and a_{0h} are defined in Table 1. $\{\xi_{1h}, h \in H_1\}$, $\{\xi_{2h}, h \in H_2\}$, and ξ_{31} were drawn independently from $\text{Uniform}(0, 0.1)$. Also, $\beta_0 = 0.06$, $\epsilon_{it} \sim N[0, (0.02)^2]$ and $b_i \sim N[0, (0.05)^2]$.

[Figure 2 about here.]

We applied both LPFR (using `lpfr()` available in the `refund` package in R (Crainiceanu et al., 2012)) and the LongPEER method with different forms of structured penalties to the simulated data. To obtain LPFR estimate, the dimension of both principal components for predictor function and truncated power series spline basis for the regression function were set to default values of 30.

Table 2 displays the MSE and prediction error obtained for different estimates. The range of SSPE for the considered methods is very narrow (1.116 and 1.168) indicating that all methods perform well when the prediction metric is applied.

The LongPEER estimate has much smaller MSE when compared to the other three estimates. Ridge estimate has less bias compared to the estimate obtained using second-order difference penalty. However, due to the larger variance, in overall, the ridge estimate has larger MSE

compared to the estimate obtained using second-order difference penalty. Both the bias and variance are largest for the LPFR estimate and consequently it has the largest MSE of the four estimates.

Figure 2 displays the four estimates of the regression function. The LongPEER estimate is almost identical to the true regression function. Bump locations and magnitudes are very close to the true function and nearly as smooth as the true function. The estimated regression function obtained using ridge penalty is also quite close to the true function including the location and the magnitude of the bumps. However, the ridge estimate is more wiggly than the LongPEER estimate. The LPFR estimate and the estimate obtained using second-order difference penalty are oversmoothed in that the magnitude of the bumps is underestimated or missed altogether. The increased performance of the LongPEER estimate is due to its ability to exploit presumed structural information which is ignored by the other estimates.

[Table 2 about here.]

5.2 Simulation with time varying regression function

[Figure 3 about here.]

In this simulation, the regression function varies as a parametric function of time. We are not aware of other longitudinal functional regression methods for estimating a time-varying regression function so we display on the performance of LongPEER. The primary goal is to assess the effects of sample size and the relative contribution of external information as determined by α_0 and α_1 in equation 7, on the regression function estimate.

Without loss of generality, we set $\alpha_0 = 1$ and vary α_1 on an exponential scale. Larger values of α_1 indicate greater emphasis of prior information on the estimation process. The model considered here is similar to that described in Section 5.1 with the exception that $\gamma(t, s) =$

$\gamma_0(s) + t \gamma_1(s)$. The function $\gamma_0(s)$ is defined in equation (9) and $\gamma_1(s)$ is of the form

$$\gamma_1(s) = \sum_{h \in H_{\gamma_1}} a_{1h} \exp \left[-2500 * \left(\frac{h-s}{100} \right)^2 \right]$$

where the value of h and a_{1h} are listed in Table 1 and $\beta_0 = 0.06$. Realizations of functional predictors were generated as described in section 5.1.

For each simulation, an appropriate σ_ϵ^2 was chosen to ensure that the squared multiple correlation coefficient $R^2 = s_y^2 / [s_y^2 + \sigma_\epsilon^2]$ is 0.9. Here, $s_y^2 = \frac{1}{4} \sum_{t=1}^4 \frac{1}{N-1} \sum_{i=1}^N (y_{it} - \bar{y}_{.t})^2$ denotes the average sample variance in the set $\{y_{it} - \epsilon_{it} : i = 1, \dots, N; t = 1, \dots, 4\}$ with $\bar{y}_{.t} = \frac{1}{N} \sum_{i=1}^N y_{it}$.

Results in terms of SSPE and MSE are displayed graphically in Figure 3. As the sample size increases, both SSPE and MSE of $\tilde{\gamma}_0$ and $\tilde{\gamma}_1$ decrease, providing empirical evidence that the estimates obtained using decomposition based penalty are consistent. For a given sample size, we observe a decrease in MSE as the value of α_1 increases up to 100. However, no further improvement is seen beyond $\alpha_1 = 100$, suggesting that choice of α_1 has little or no influence the estimate provided it is sufficiently large.

The estimated γ_0 and γ_1 are displayed in Figure 4. The estimated $\gamma_0(\cdot)$ and $\gamma_1(\cdot)$ are nearly identical to the simulated true functions, even for sample size $N = 100$. Further inspection reveals a small estimation bias at the points where both γ_0 and γ_1 have peaks, but this bias gradually disappeared as the sample size increased to $N = 400$.

[Figure 4 about here.]

6. MRS study application

[Figure 5 about here.]

We applied LongPEER to study the association of metabolite spectra obtained from basal ganglia on the global deficit score (GDS) in a longitudinal study of late stage HIV patients

(Harezlak et al., 2011). GDS is often used as a continuous measure of neurocognitive impairment (e.g., Carey et al., 2004) and a large GDS score is an indicator of high degree of impairment. The collected MRS spectra are composed of the combination of pure metabolite spectra, instrument noise and baseline profile. The spectra were sampled at $n = 399$ distinct sampling points each. We collected a total of $n_{\bullet} = 306$ observations from $N = 114$ subjects. The longitudinal observations for each subject were within 3 years from baseline. The number of observations per subject ranged from 1 to 5 with median 3.

Information on spectra obtained from nine pure metabolites was available and hence we were able to use this to define a decomposition penalty L_Q as in equation (7) (with $\alpha_1 = 1000$). Spectra of basal ganglia at baseline and pure metabolite spectra are displayed in Figure 1. The pure metabolite spectra include spectra of Creatine (Cr), Glutamate (Glu), Glucose (Glc), Glycerophosphocholine (GPC), *myo*-Inositol (Ins), N-Acetylaspartate (NAA), N-Acetylaspartylglutamate (NAAG), *scyllo*-Inositol (Scyllo) and Taurine (Tau). It can be verified that at each locations of major bumps in basal ganglia spectra (left panel), there are bumps in at least one of pure metabolite profiles (right panel). We fitted the following model to data

$$y_{it} = \beta_0 + \beta_1 t + \int_{\Omega} W_{it}(s) \gamma(t, s) ds + b_i + \epsilon_{it}, \quad (9)$$

where, $\gamma(t, s) = \gamma_0(s) + t \gamma_1(s)$ and y_{it} and $W_{it}(\cdot)$ are the GDS and basal ganglia spectrum for subject i at time t , respectively. We assume that $\epsilon_{it} \sim N(0, \sigma_{\epsilon}^2)$ and b_i is the subject-specific random intercept distributed as $N(0, \sigma_b^2)$. The estimates are obtained as the BLUP from the mixed model formulation described in Section 4.1.

Estimates of σ_{ϵ}^2 and σ_b^2 were 0.08037 and 0.33115, respectively. Figure 5 displays the estimates of $\gamma_0(\cdot)$ and $\gamma_1(\cdot)$ with pointwise 95% confidence bands. To make the interpretation easier, we also include the selected pure metabolite spectra. These figures reveal that $\hat{\gamma}_0(\cdot)$ (the ‘baseline’

part of the regression function) is different from zero at the locations where at least one of the pure metabolites Cr, Glu, NAA, NAAG and Scyllo has a bump. Similarly, each non-zero part of $\hat{\gamma}_1(\cdot)$ (the ‘longitudinal’ part of the regression function) coincides with bump locations of one or more pure metabolite profiles of Cr, Glu, NAA, GPC and Ins.

Pointwise confidence interval for $\gamma_0(\cdot)$ and $\gamma_1(\cdot)$ contain the “zero” line over most of the intervals of interest. The estimated γ_0 is significant in the region $s \in (0.4, 0.5)$ and estimated γ_1 is significant in a wider region of $s \in (0.4, 0.6)$. To be precise, the peaks of the both $\hat{\gamma}_0(\cdot)$ and $\hat{\gamma}_1(\cdot)$ are significant at the locations where the at least one of the pure metabolite profiles of NAA and Glu have bumps.

The finding of the significant negative ‘longitudinal’ effect of NAA is worth noticing. This suggests that GDS increases as the NAA concentration decreases in basal ganglia. This finding is consistent with the studies where reduced concentration of NAA has been found to be associated with decrease in neuronal mass (Christiansen et al., 1993; Lim and Spielman, 1997; Soares and Law, 2009).

7. Discussion

We have proposed a novel estimation method for longitudinal functional regression and derived some properties of the coefficient function estimate. Within this framework, the LongPEER method is the first to allow a coefficient function to *vary with time*. It extends the scope of generalized ridge regression to the realm of longitudinal data. The approach may be viewed as an extension of longitudinal mixed effects models, replacing scalar predictors by functional predictors. Advantages of this method include: 1) a framework that allows the regression function to vary over time; 2) the ability to incorporate structural information into the estimation process; and 3) easy implementation through the linear mixed model equivalence.

The emphasis here is on a general statistical framework for incorporating scientific knowledge into the estimation process when both the scalar response and predictor functions are observed longitudinally. In absence of prior information, one may impose more vaguely-defined constraints—such as smoothness or re-weighted empirical subspaces—to estimate the coefficient function. An advantageous use of specific prior information is illustrated in the first simulation where smoothness constraints or a spline basis representations perform poorly. The second simulation shows a reduction in estimation error as sample size increases; this empirically suggests the consistency for such an estimate, provided the information about the regression function structure is correct.

Solutions to the generalized ridge regression problem can be expressed in many forms. The linear mixed model equivalence provides an easy computational implementation as well as an automatic choice of the tuning parameters using REML criterion. The GSVD provides algebraic insight and a convenient way to derive the bias and variance expressions of the estimates. Another natural way to obtain the regression function estimates is by using Bayesian equivalence (see e.g., Robinson, 1991) with the informative priors quantifying the available scientific knowledge.

One of the natural extensions of our work can incorporate multiple functional predictors. For example, we can observe two functional predictors $W_t^{(1)}(\cdot)$ and $W_t^{(2)}(\cdot)$ with $\gamma^{(1)}(t, \cdot)$ and $\gamma^{(2)}(t, \cdot)$ their associated coefficient functions, respectively. Furthermore, we can express $\gamma^{(1)}(t, s) = \gamma_0^{(1)}(s) + f_1^{(1)}(t)\gamma_1^{(1)}(s) + \cdots + f_d^{(1)}(t)\gamma_d^{(1)}(s)$ and $\gamma^{(2)}(t, s) = \gamma_0^{(2)}(s) + f_1^{(2)}(t)\gamma_1^{(2)}(s) + \cdots + f_d^{(2)}(t)\gamma_d^{(2)}(s)$. If $W^{(1)}$ and $W^{(2)}$ represent design matrices for the two functional predictors, then we can estimate $\gamma^{(1)}(t, \cdot)$ and $\gamma^{(2)}(t, \cdot)$ by finding the BLUP estimate of $\gamma^{(1)}$ and $\gamma^{(2)}$ from the mixed model, $y = X\beta + W^{(1)}\gamma^{(1)} + W^{(2)}\gamma^{(2)} + Zb + \epsilon$. The simplified formula for bias and variance derived in Section 3.2 still holds with an additional assumption $(W^{(1)})^\top V^{-1}W^{(2)} = 0$.

As presented here, the method addresses models having a continuous scalar outcome, but allowing for either binary and count responses is of interest. Indeed, an important problem that arises in MRS data is that of understanding the neurocognitive impairment status of HIV patients, defined as a binary variable, based on functional predictors collected over time. Extending our approach to these general settings is possible and currently being pursued.

				70	0.15		
				80	0.03

Table 2

Estimation and prediction errors obtained using Ridge penalty, second-derivative penalty (D^2), LPFR and LongPEER based on 100 simulated datasets. The sample size is set at $N=100$ and number of observations at $n_i = 4$.

	LPFR	Ridge penalty	D^2 penalty	Decomposition penalty
MSE(γ_0)	0.2227	0.0980	0.0820	0.0095
$ \text{Bias} ^2(\gamma_0)$	0.1065	0.0099	0.0551	0.0006
Trace of Variance(γ_0)	0.1162	0.0881	0.0269	0.0089
SSPE of Y	1.1685	1.1157	1.1579	1.1535
